PARABIOSIS AND XIPHOPAGI.

The term parabiosis was introduced into biology to express the condition which results when two animals are artificially united in such manner as to constitute a single organism. It was first performed about fifty years ago by suturing together two rats by raw surfaces of skin. Vascular anastomosis promptly resulted and when when atropine was injected into one of the animals its action was at once manifested in the other. In quite recent years this experiment has been amplified by making an enteroanastomosis between the parabiotic animals (rabbits). The latter must be young and should preferably be of the same sex for the complete success of the experiment. The animals soon begin to exhibit a correlation of acts, as if moved by common nerve centers. If one animal dies the other soon succumbs, apparently from absorption of ptomains; but if at once separated from its fellow it survives. If both kidneys are removed from one animal, both animals die of uremia, and the intact one is the first to show the symptoms. Many other interesting data have been accumulated along this line of research.

In the *Berliner klinische Wochenschrift* for June 19 Coenen calls attention to the parallelism which is evident between parabiotic animals and human xiphopagi, the latter exhibiting many of the phenomena of parabiosis, such as result from a common systemic circulation. A few paradoxical exceptions occur; for example, in one case chloroform inhalation by one was without effect on the other of the xiphopagous twins. The chief interest in this biological question relates to the possibility of separating xiphopagi and other double monsters capable of extended survival, without prejudicing their vital integrity. As is well known, this was partially effected on the so-called Brazilian twins in 1900, one of the twins surviving, while the other died of pleurisy and pneumothorax in the sixth postoperative day. The twins were united by their sterna and a bridge of hepatic tissue while there was an anastomosis between the pleural, peritoneal, and pericardial sacs. Owing to the imperfect results the expediency of such operations has naturally been called in question.

Xiphopagi are by no means rare, for as far back as 1861, 114 had been placed on record. The fact that in two cases separation was readily effected, and this in preaseptic days, tends to show that the bridge in such cases was composed of skin, fibrous tissue, and cartilage only. When the Maria-Adele xiphopagæ were separated in 1881 a small bridge of liver and peritoneum required division and the intervention ended fatally for both twins. According to Coenen of ten twins thus far operated upon, one-half have died from the intervention.

SYNERGISM AND THE FULL UTILIZATION OF DRUG ACTIVITY.

While synergistic drugs have been used intelligently for decades, their employment has been largely empirical. Purgatives, for example, have usually been given in combination, first upon the merely cumulative plan, and later in order to combine remedies which act upon different portions of the alimentary canal, or which induce purgation in different ways. Combination naturally favors economy in the use of the individual drug, since the single dose can thereby be made smaller; and it is probably true as a general proposition that two drugs which act well as synergists will not exhibit any parallelism as to unpleasant over-action, collateral effects, or sequelæ. It not infrequently happens that good synergists neutralize the undesirable effects of each other. Synergists occur side by side in drugs—as morphine and codeine in opium, strychnine and brucine in nux vomica; and pharmacists have striven for years so to manipulate fluid extracts as to eliminate all but the synergistic ingredients, thereby getting rid of useless ballast and non-synergistic active principles. With the great development of synthetic remedies it has also become possible to introduce the principle of synergism in this field. With all these advances, however, little has been done in the exact quantitative or biometric direction. Bürgi of Berne has devoted much time and labor to pioneer work in what he calls "the action of mixtures." One of his articles appears in the *Berliner klinische Wochenschrift* for May 15. His work is founded on hundreds of experiments and his results often differ greatly from theoretical deductions. Thus if x is a narcotic drug, Nx may represent the minimum narcotic dose when given alone. If y is a second narcotic drug Ny represents its minimal dose. In theory a combination would be represented by ½ Nx + ½ Ny. But experiment shows that ¼ Nx + ¼ Ny will give the desired narcotic effect. Thus in combination each remedy doubles the activity of the other, so that the actual amount of medicine given is practically decreased by combination. Even more surprising effects are in evidence if one drug is somewhat increased while the other is greatly diminished. Thus, Bürgi has obtained narcosis by such formulæ as these: 2/5 Nx + 1/25 Ny; ¾ Nx + 1/100 Ny, and ½ Nx + 1/80 Ny. This principle is in evidence throughout the entire domain of therapeutics. The remarkable effects of certain mineral waters are set down in part to the synergism of small amounts of salts in solution. It would seem as though terms such as synergism and full economy of drug power are hardly strong enough to do justice to such remarkable "phenomena." It may, perhaps, be more fitting to state that a certain quantity of one drug is able to activate a certain quantity of another drug, using the verb to activate in the ordinary biochemical sense.

New York City Passes the 5,000,000 Mark.—On August 3, 1911, the population of the City of New York reached an estimated total of 5,000,407, distributed by boroughs as follows: Manhattan, 2,393,636; The Bronx, 487,437; Brooklyn, 1,716,852; Queens, 312,630; Richmond, 89,852. The population of the Greater City, July 1, 1898, was 3,272,418, and during these thirteen years the city has increased 53 per cent.

News of the Week.

Cholera Reports.—Cases of cholera have been reported in several points in France, in Trieste, Austria, and in Yucatan. No cases have been developed in New York, and but few suspicious cases have been found among the immigrants from infected ports. One death from the disease has occurred in Boston, the mode of infection in the case not being ascertainable.

Bellevue Hospital.—The one hundredth anniversary of the founding of Bellevue Hospital occurred recently. On July 29, 1811, the cornerstone of the original building was laid on land originally known as Kip's farm, which had been acquired by the city a few months before.

Vital Statistics.—For the week ending July 29 the Health Department of New York announces a total of 375 deaths from all causes among infants under one year, a decreases of 170, as compared with the corresponding week of last year. From diarrheal diseases alone there were 179 deaths during the week, as compared with 334 in the same time in 1910, a decrease of 155. Since January 1, 8,583 babies under one year have died from all causes in New York, while in the same period of 1910 there were 9,471 infant deaths.

The French Birth Rate.—The population of France in 1910 was 39,252,245. During that year there were 774,358 births and 703,777 deaths, making the net excess of births over deaths 70,581. In the previous year the excess of births over deaths was only 13,424, the number of deaths having been 52,768 greater than in 1910. In certain sections of the country the death rate considerably exceeded the birth rate. For the five-year period from 1901-1905, the number of births per 1,000 of population in some of the leading European countries was as follows: In Holland, 155; in Germany, 149; in Great Britain, 121; in Austria, 113; in Italy, 106, and in France, 18.

Health of the Canal Zone.—The report of the Department of Sanitation of the Isthmian Canal Commission for the month of May, 1911, gives the total number deaths from all causes among employees as 44, of which 33 were due to disease, and 11 to violence, giving an annual average per thousand of 10.89. The annual average death rate among employees in May previous years was as follows:

1904	5.35
1905	16.65
1906	24.79
1907	30.15
1908	10.44
1909	9.45
1910	7.72
1911	10.89

Including both employees and civil population, the death rate in the cities of Panama and Colon and in the Canal Zone for May of each year was as follows:

1905	41.96
1906	42.32
1907	31.57
1908	20.87
1909	15.77
1910	18.69
1911	22.32

Among employees 5 deaths were due to nephritis, 6 to lobar pneumonia, 6 to malarial fever, 4 to tuberculosis, and 2 to typhoid fever. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Health Department Bulletin.—The demand for copies of the Monthly Bulletin issued by the Department of Health of the city of New York has become so great that it has been found necessary to increase the edition very largely. Hereafter physicians resident in New York desiring to receive the Bulletin may have their names placed upon the mailing list for free copies upon application to the editor, Monthly Bulletin of the Department of Health, Fifty-fifth Street and Sixth Avenue.

The Pennsylvania State Department of Health.—Dr. Samuel G. Dixon, Pennsylvania State Health Commissioner, claims that his State is doing more to aid the country practitioner of medicine in his daily work than any other Commonwealth. Since 1906 48,760 examinations of water, sputum, blood, tissues, etc., have been made by the State laboratories for physicians practising outside of municipalities. Widely distributed throughout the State at convenient points are 65 stations where diphtheria antitoxin can be procured gratuitously for indigent patients. Also there are 67 stations where tetanus antitoxin can be obtained under the same conditions for a like class of patients. Further the department furnishes on request of attending physicians printed directions as to the sanitary precautions to be observed by those in charge of cases of communicable disease. Finally, the State is doing successful work for the tuberculous poor at Mount Alto Sanatorium and through the 115 dispensaries conducted by the department in different parts of the State.

Typhoid Outbreak.—An epidemic of typhoid fever among the employees of the Colony Club of New York has made it seem advisable to close the clubhouse. Dr. Charles E. North has undertaken an investigation of the sanitary conditions of the building.

Mr. Nathan Straus has been appointed by President Taft to represent the United States at the Third Internations Congress for the Protection of Infants, which is to be held in Berlin on September 11 to 15, and also at the Seventh International Congress on Tuberculosis, which will be held in Rome some time next year.

The Babies' Dairy.—The incorporation of the Babies' Dairy in New York City, for the purpose of supplying proper food for infants and children suffering from nutritional disorders and other diseases of childhood, was recently effected. Among its objects are the maintenance of a proper place or places for the supply and distribution of food, the supervision my physicians of children suffering from disorders of malnutrition, and the education of mothers in and care and feeding of infants.

No State Sanitary School.—Governor Dix recently vetoed the bill passed at the last sessions of the New York State Legislature appropriating $10,000 for the establishment at Cornell University of a State School of Sanitary Science and Public Health. This action was taken by the Governor because of the condition of the State funds.

New York Milk Stations.—Commissioner Lederle of the New York City Department of Health has sent to the Board of Estimate an urgent request for additional funds to meet the increasing demands on the milk stations in the city. On July 22 milk was supplied to 9127 babies, an increase of 2674 over the number applying on July 1. The commissioner asks for ten additional inspectors and

twenty-five additional nurses to be assigned to the stations. At present some of the nurses have to look after between two hundred and three hundred babies apiece.

Havana Not Infected.—A contradiction has been issued of the rumor that some cases of yellow fever had appeared in Havana and that typhoid fever was prevalent. On the contrary, it is said, the health of the city has never been more satisfactory.

Hospital for Tuskegee.—The Tuskegee Institute in Alabama has received a gift to be used for the erection of a hospital in connection with the institute, to be known as the John A. Andrew Hospital. The name of the donor has not been announced.

Eighth District (S. C.) Medical Association.—At the annual meeting of the association, comprising the Counties of Lexington, Bamberg, Orangeburg, and Calhoun, which was held at St. Matthews on July 18, the following officers were elected: *President*s Dr. T. H. Dreher of St. Matthews; *Vice-President*, Dr. J. S. Matthews of Denmark; *Secretary-Treasurer*, Dr. Sophia Brunson. The next meeting will be held in Orangeburg.

Big Horn Medical Association of Wyoming.—At a recent meeting, held in Baslin, the following officers were elected: *President*, Dr. C. Dana Carter, Basin; *Vice-President*, Dr. R. M. Hamilton, Grayboull; *Secretary*, Dr. George A. Harris, Basin; *Treasurer*, Dr. Torgeson, Lowell.

Lehigh Valley (Pa.) Medical Association.—The annual meeting of this society was held at the Delaware Water Gap on July 21, when the following officers were elected for the ensuing year: *President*, Dr. C. B. Smith, Washington; *Vice-Presidents*, Dr. E. H. Kistler, Lansford; Dr. P. F. Lyttle, Birdsboro; Dr. A. H. Hornbeck, Catasauqua; *Secretary*, Dr. J. W. Luther, Palmerton; *Assistant Secretary*, Dr. J. H. Santee, Palmerton; Treasurer, Dr. A. A. Seem, Bangor.

The Medico-Legal Society of Rhode Island became a duly chartered State organization at a meeting held on July 20. The objects of the society are the investigation, study, and advancement of medical jurisprudence, particularly as related to crime and its punishment, the public morals, health, and welfare. The following officers were elected: *President*, Judge Benjamin W. Grim, Cranston; *Vice-President*, ex-Senator Daniel A. Lathem; *Secretary-Treasurer*, Dr. Carl R. Doten.

The Medical License Law in Alaska.—Two years ago last February, largely through the efforts of Dr. Harry Carlos DeVighne of Douglas, Alaska, Congress was induced to pass a medical law for Alaska. Previous to this time there was no law regarding the practice of medicine in the territory. The first case to be tried under this law resulted on July 20 in the conviction and imprisonment of a man at Juneau for practising medicine without having secured a license.

Obituary Notes.—Dr. William Cullen Bryant of Brooklyn, New York, a graduate of the New York Homeopathic Medical College in 1871, and a member of the American Institute of Homeopathy, the Homeopathic Medical Society of the State of New York, and the Kings County Homeopathic Society, died at his home of nephritis on July 22, aged 62 years.

Dr. Albert G. B. Hinkle of Philadelphia, a graduate of the Medical Department of the University of Pennsylvania in 1857, a veteran of the Civil War, and later a police surgeon in the city of Philadelphia, and a member of the American Medical Association and the State and county medical societies, died at his home on July 19, aged 80 years.

Dr. Julia Hibben Flagg of Vancouver, Washington, a graduate of the Medical College of Indiana in 1890, and a member of the Clarke County and Washington State medical societies, and of the Portland, Ore., city and county medical societies, died at her home on June 2 from injuries received in a runaway accident while returning from a professional call.

Dr. W. L. Pollock of Boone, Iowa, a graduate of the Jefferson Medical College, Philadelphia, in 1871, and a member of the American Medical Association, and the Iowa State and Boone County medical societies, died suddenly on July 15, aged 61 years.

Dr. Franz B. V. Becker-Laurich of Brooklyn, New York, a graduate of the Long Island College Hospital in 1893, and a member of the New York State and Kings County medical societies, died at his home on July 27.

Dr. Isaac Adams of Annisquam, Mass., a graduate of the Harvard Medical School in 1862, died at his home on July 24, aged 75 years.

Dr. W. J. Castleberry of Lincoln, Ala., a graduate of the Medical Department of the University of Georgia in 1872, died at his home after a short illness on July 14, aged 63 years.

Correspondence.

FINLAY'S WORK ON YELLOW FEVER.

To the Editor of the Medical Record:

Sir:—My attention has recently been called to your most excellent editorial of April 22, giving due credit to Dr. Charles J. Finlay for his genius in observing the facts and from them forming a correct idea of how yellow fever is transmitted. Though he was born in Cuba, the Scotch really claim him and are particularly proud of his work and his persistence in forcing it to attention. Considering the times, it will eventually be considered one of the most wonderful pieces of constructive work in the history of medicine, but like every other advance it was rejected by contemporaries. Unlike nearly all other great medical discoverers, however, he has lived to see the acceptance of his facts and has not had to die of a broken heart; but it has been enough to break anyone's heart to see himself so utterly ignored while the world has been singing the praises of the men upon whom he forced his ideas. It is so like praising the builder of a beautiful church and ignoring the architect who conceived it. No doubt Reed himself, if alive, would blush at the methods used, and would continue to insist upon giving Finlay full credit for the great conception. Too high praise cannot be given also to Lazear and Carroll for their bravery, but Finlay did the same self-inoculation twenty years earlier. Finlay, indeed, used these Americans as one would a tool, and he had to force them, for they, too, laughed at him.

It seems to me that the credit for initiating the experiments confirming Finlay's discovery is due to Leonard Wood, who, as Governor, forced the matter along in the very city where Spanish generals had positively prohibited such work. It was a time, too, when military satraps the world over were doing their utmost to hamper the new sanitation as to

malarial extermination. The stories printed as to their interference with the treatment of the sick make very sad reading. So the possibility of success was due entirely to the wonderful foresight and ability of this exceptional man who has been successful in every position he has occupied.

A Lover of Justice.

Edinburgh, July 15, 1911.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL COMMISSION ON TUBERCULOSIS—FINAL REPORT — CONSUMPTION DISPENSARIES — SANATORIUM TREATMENT DISCUSSED IN PARLIAMENT—MEDICAL NEWS—OBITUARY.

London, July 14, 1911.

The final report of the Royal Commission on Tuberculosis was issued on Wednesday, and gives the results of the research in which it has been engaged for the last ten years. Though the "Final Report" of this commission, the work is confessedly incomplete, and research will still go on concerning many questions connected with tuberculosis. The members of the commission were Sir W. H. Power, Dr. Sirus Woodhead, Dr. Sidney Martin, Sir J. McFadyean, and Sir Rubert Boyce. The last named died, as I reported, before the issue of the report on which he had labored assiduously. The commission was to consider: (1) Whether the disease in animals and man is one and the same. (2) Whether animals and man can be reciprocally infected with it. (3) Under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances favorable or unfavorable to such transmission. The answer given to the first question is practically "Yes," as far as the public health is concerned; for, notwithstanding differences in the characteristics of the two forms of bacilli, it is shown that human beings can be infected by the bovine form. To the second question the answer is also "yes," as might be expected from the reply to the first. As to the third question, further research is needed on some points, but the milk of tuberculous cows is decided to be the chief cause of human infection by the bovine bacillus. In fact, a considerable amount of tuberculosis in childhood is to be ascribed to the bovine form, which reaches the children in cows' milk, and it is evident that the agitation for more effective precautions against the distribution of tuberculous milk has been more than justified. Further, the crusade against consumption now being waged must be largely directed against milk infection; for, although phthsis in adults is, with few exceptions, due to the human bacillus, the various forms of tuberculosis in children are no less important. Even adult man is not immune to the bovine variety. The report considers the three types of bacillus—human, bovine, and avian, and the methods by which they are differentiated, but this must not detain us. The results of one hundred and eight cases of human tuberculosis are recorded, none of them being lupus. In fourteen only the human bacillus was found. In twenty-eight others it was the same in twenty-six, but in two it was bovine, and these two cases were of young adults, and were "definite cases of pulmonary tuberculosis caused by bovine bacilli, and, as far as could be ascertained during life, cases of primary pulmonary tuberculosis. In neither was there any evidence of tuberculous disease elsewhere." These patients died, and the cause in one was stated to have been phthisis, the other seemed generalized tuberculosis, but no post-mortem could be obtained in either. Another group of cases was formed of twenty-nine infants and children, all suffering from primary tuberculosis of the stomach. Of these fourteen yielded bovine and thirteen human bacilli; in the other two there was a mixture of the two varieties. Of the total one hundred and eight cases eighty-four gave human tubercle bacilli only, nineteen yielded bovine tubercle bacilli only, and five gave both. The commissioners hold that though the bovine may be solely responsible for some cases of consumption, and may be present with the human bacillus, the majority of cases infected by the bovine are cases of alimentary tuberculosis, such as those of the cervical glands and primary abdominal cases. These last are cases in which the "bacillus has unquestionably been swallowed."

The report gives some very important information about lupus. In nine cases the bacillus exhibited the cultural characteristics of the bovine form, but in only one of them did it possess the high virulence as well. In the other eight it was less virulent, not only for the calf and rabbit, but also for the guinea-pig and monkey. It was found possible in two cases to bring up the virulence to the usual degree by residence in the tissues of the calf and rabbit.

Pork being so largely consumed, the prevalence of swine tuberculosis is of great importance. In fifty-nine cases investigated fifty yielded the bovine, three the human, five the avian, and one a mixture of bovine and avian forms. This shows there is danger from pigs, and the commissioners admit as much, but they regard the risk of infection from birds as negligible. But the danger from cows is very great, and they say it is not necessary for the cow to have tubercle in the udder for the milk to be infected. Any tuberculous cow is dangerous.

The commissioners express the conviction that the prevention of the ingestion of bovine bacilli in milk would greatly reduce tuberculosis of the cervical and abdominal glands in children. They would therefore exclude from the food supply the milk of any tuberculous cow, irrespective of the site of its disease. Further, in the interests of infants and children, who are specially endangered, they urge that existing regulations as to milk and meat should not be relaxed, but, rather, enforced throughout the kingdom, and so increased as to afford better security against the infection of human beings through articles of diet derived from tuberculous animals.

The foregoing is but a first glimpse at this important report, which cannot fail to be studied in all its respects, for it appears at a time when the public is excited on the subject, Parliament is occupied with it, and the profession is glad to receive so practical an addition to its researches.

Showing, too, the public interest, a powerful appeal has been made for a central fund to support a crusade in favor of tuberculin dispensaries. This appeal is signed by Lord Glenconner, chairman, and Sir Alex. Henderson, treasurer, and asks for £100,000, of which more than £26,000 has been subscribed. Since I wrote to you about one of these dispensaries four or five others have been opened. It is said that each costs about £1,000 to maintain efficiently. One advantage of the dispensary is that it follows the patient to his home and gives the

more important instruction as to preventing the spread of infection and making the home healthy.

On Wednesday night the House of Commons debated the government's proposal (in connection with the insurance scheme) to devote £1,500,000 to build "a chain of sanatoria" across the country, and a million more annually to maintain them. Mr. Austin Chamberlain moved the exclusion of this provision from the bill. He questioned the propriety of including the treatment of a special disease in our insurance bill, and asked, if consumption was to be thus provided for, was there not reason to extend the plan to cancer? Funds obtained from national insurance should rather go to a campaign to improve national health, and a special case be otherwise met.

Mr. Walter Long also objected to the scheme; said other diseases caused more misery, and the evidence of the value of sanatoria was not conclusive.

Dr. Addison maintained that the data available justified the proposal. He said medical men had no knowledge as to the prevention of cancer, but much as to the prevention of tuberculosis. In Germany it had been shown that the earning power of patients was greatly increased after sanatorium treatment. He declared that our friendly societies are spending more than a million a year in this treatment. Dr. Hillier, another medical member, followed on rather different lines. He would support any effort on the part of the State to deal with tuberculosis, but he pointed out that the proposal to treat only insured persons was not statesmanlike. The families of those treated would continue to spread the disease, and unless the plan were extended and supplemented it would merely become a costly luxury for a few. Other speakers followed with similar criticisms, and Mr. Lloyd George replied at length. He had been well primed, and poured out statistics, but made no attempt to confute the medical member of parliament, although he spoke as if he were himself an authority on such questions. He said there was an improvement year by year in the results obtained in sanatoria, and they gave an increased chance to the man who was struggling for life. He had no objection to supplementary treatment. It was impossible at once to provide for some 200,000 or 300,000 patients, and the people of this country preferred to go step by step. It was an experiment he had proposed, and it would be a mistake to go further until it was seen how this worked out. He further intimated that he would be willing to extend it as success attended, and pointed out how the Treasury might join local authorities in doing so.

At the Royal Society of Medicine, Sir Henry Morris has been elected president for the session 1911-12. Sir W. S. Church and Sir F. C. Champneys are the new Hon. treasurers; Mr. Arthur Latham and Mr. H. S. Pendlebury Hon. secretaries.

Queen Alexandra and the Empress Marie of Russia visited the Radium Institute on Monday, and were shown the effect of radium rays on bacteria and other organisms, as well as their penetrating power in regard to lead and other substances. The effect of the rays on various minerals, including diamonds, was also shown. On a later day a visit was made to the museum of the College of Surgeons.

Sir William Osler on Monday unveiled in the Chapter House of Reading Abbey the memorials to the first and last abbots presented to the town by Dr. Jamieson B. Hurry as a coronation gift.

The King has received from Lord Iveagh a gift of £50,000 to distribute at His Majesty's pleasure to Dublin hospitals and the consumption hospital at Newcastle, Wicklow. His Majesty has appointed a committee to carry out the donor's intention.

The Hon. Whitelaw Reid distributed the prizes at the London Hospital yesterday afternoon.

The death of Mr. Furneau Jordan, J. P., has occurred at the age of eighty-one. Mr. Jordan was for many years a leading consulting surgeon in the midland counties. He was surgeon and then consulting surgeon of the Queens Hospital, Birmingham, and professor of anatomy and surgeon in the Queens College, which now is a part of the University. He also held other surgical appointments in the Women's Hospital, the Dental, the Skin Hospitals, and some others in midland towns. He had served as president of the Midland Medical Society. He has for some years lived in retirement in Devonshire. He qualified in 1854, and became F.R.C.S. in 1866. He took M.B., Ph.B., at the Royal University of Ireland, and later, when the Birmingham University was established, the same degrees in that. He published "Notes on One Hundred Consecutive Cases of Abdominal Section," 1897, and "After Effects of Removal of Appendages and Uterus," 1899, in the *Gynecological Journal,* and contributed other papers to the *Birmingham Medical Review,* and other periodicals.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

TREATMENT OF CALCULUS OF THE KIDNEY—TREATMENT OF ANEURYSM OF THE AORTA—TREATMENT OF RENAL TUBERCULOSIS—NECROLOGY.

PARIS, July 15, 1911.

POUSSON of Bordeaux has made a study of the question of the best route for the extraction of renal calculi, which is of prime importance at present. Should we do nephrotomy or pyelotomy? Pousson thinks that there are circumstances in which extraction by the transrenal incision presents more of a guarantee of effectiveness than section of the pelvis of the kidney. Pyelotomy is indicated especially when the calices and pelvis, distended or not, contain single concretions or a small number of them, whose surface, although irregular, presents no prolongations which can be broken off and left in the passages unknown to the operator; these characteristics may be recognized by preoperative radiography. Not only may the concretions be extracted whole by incision of the pelvis, but also infection of the kidney may be victoriously combated by lavage and drainage sufficiently prolonged. Nephrotomy, on the contrary, is indicated when the concretions are voluminous and branching, occupying with their many branches the most of the calices, and being prolonged even into the parenchyma of the kidney, which they have crowded back into pockets, to the walls of which they are adherent very strongly. Nephrotomy cannot be reserved for those cases in which the functional value of the kidney is nil. Indeed, the surgery of kidney calculus should be above all conservative, for lithiasis being generally diathetic we should always fear that after it has manifested its effects on one kidney, on which we are called upon to operate, it may later attack the opposite organ.

An interesting observation was detailed by Cuneo with reference to the surgical treatment of aneurysm of the aorta. It concerned a woman 49 years of age, who had an aneurysm of the ascending por-

tion of the arch of the aorta. Cuneo made a ligation of the brachiocephalic trunk. Under its influence the patient had a marked amelioration of the symptoms. She lived five years after the operation. Jean-Louis Faure reported a similar case of ligature of the brachiocephalic trunk in an aneurysm of the aorta. The operation was a perfect success, and the patient died three years after without a rupture of the aneurysm, discharging blood from the mouth. Savariaud showed that direct intervention on the sac of the aneurysm is destined to be unsuccessful; on the contrary, operations which are based on the coagulability of the blood in the aneurysm, whenever they diminish the rapidity of the current of blood, give excellent results.

Leon Bernard published an article on the treatment of renal tuberculosis. Should we to-day do nephrectomy early when we have to deal with a unilateral tuberculosis of the kidney, or should we treat the patient by the subcutaneous injection of tuberculin? The progress made in diagnostic and operative technique, the demonstrative value of the results obtained everywhere, thanks to that technique, have little by little conquered all surgeons, and brought them to the doctrine that has been maintained for years by Albarran in regard to the treatment of renal tuberculosis; that is, since the discussions that took place in the Congress of Urology and in the learned societies of France and elsewhere, the conclusion is justifiable that in renal tuberculosis early nephrectomy in demanded, whenever there is no contraindication to that necessary and curative operation. Now, a movement which began abroad seems to be beginning here, which tends to substitute for this rational conduct the non-operative treatment by tuberculin. The conclusions arrived at by Bernard are these: First, unilateral renal tuberculosis (with caseous infiltration) demands early nephrectomy, as soon as diagnosis has been made; second, tuberculin therapy, which has not actually cured cases as a result, cannot modify this indication, which results from fifteen years of work and discussion by urologists; third, medical treatment, including the so-called specific treatments, should be reserved for cases in which surgery is contraindicated (bilateral generalized tuberculosis which is inoperable) and recurrences in the opposite kidney.

Dr. GUINARD.—A lamentable drama unrolled itself at the Hôtel-Dieu, in Paris. Guinard, surgeon to that hospital, fell assassinated by the murderous blows of a man who some months before had been under his professional care. Guinard was about to leave his wards and was slowly going away with his assistants when the assassin drew a revolver upon him and fired five shots, four of which struck him in the abdomen. Carried immediately to the operating room in which he himself had so often operated, laparotomy was done on him, and six perforations of the intestine were found and sutured. The severity of the wounds caused grave fear of the results of the operation, and in spite of a momentary rally Guinard rapidly succumbed, showing magnificent courage. Knowing himself mortally wounded, he discussed the case with his colleagues, to whom he gave himself up with a firmness of mind and a heart less anxious than those of his friends who assisted at the scene, and full of true greatness. Guinard died nobly, showing that he was one of the men of courage and devotion, noble heart, and disinterested zeal, whose example will remain a powerful and durable memory to us. The obsequies were conducted publicly in the city of Paris. The coffin was placed upon a catafalque at the head of the grand staircase of the court of honor of the Hôtel-Dieu, in which were present, besides the representatives of the Government, many deputies and senators, Agrégé Professors of the Faculty, and Members of the Academy of Medicine and Surgical Society. In this court draped in mourning, before a mute audience, were pronounced discourses by the President of the General Council of the Department of the Seine, and by the Director of Public Assistance. Finally, Dr. Jalaguier closed the ceremonies, as president of the Surgical Society. Guinard has made himself known by many interesting communications on appendicitis, perforations of the duodenum, and traumatic lesions of the intestines and liver.

OUR BERLIN LETTER.

(From Our Regular Correspondent)

ANNUAL MEETINGS OF GERMAN MEDICAL SOCIETIES—DISINFECTION OF HANDS AND OPERATIVE FIELD—GRAVES' DISEASE—RADIOGRAPHY WITHOUT A SCREEN-GRAFTING—NON-OPERATIVE TREATMENT OF MALIGNANT GROWTHS—LIGATION OF BRANCHES OF PULMONARY ARTERY IN THE TREATMENT OF PULMONARY DISEASE—FIXATION OF CECUM—RÖNTGENOLOGY OF ALIMENTARY CANAL—THERAPEUTICS OF X-RAYS—DIATHERMIA FROM HIGH-FREQUENCY CURRENTS IN GONORRHEAL ARTHRITIS, GOUT, AND RHEUMATISM.

BERLIN, May 15, 1911.

THE meetings of the large German societies, including those of surgery, internal medicine, orthopedics, and röntgenology, which meetings usually are held in the week following Easter, are over. They brought out a large number of interesting papers. In this letter it is possible to refer only to certain striking passages in these papers, and only to papers read before the congresses held in Berlin.

At the fortieth meeting of the German Surgical Society Küttner of Breslau discussed the subject of the disinfection of the hands and of the operative field. He concludes that the newer mercurial preparations are not superior to iodine, and that pure alcohol is the best disinfectant for the hands. For the operative field the best antiseptic is the 5 per cent. tincture of iodine. Kocher of Berne, in his review of Graves' disease, concludes that this condition is a hyperthyreosis, that is, a manifestation of oversecretion of the thyroid together with an increase in its iodine content; this is to be met by operation in the early stage, when the danger is small and the result certain. Bauer of Breslau has succeeded in practising radiography without a screen. By means of bandages impregnated with platinum-bariumcyanate, and wrapped about the part to be examined, he has been able not only to make a better topical diagnosis but also to perform extractions and repositions to better advantage. Lexer of Königsberg read a paper on free grafting. In making skin-grafts it is important to allow the wound to bleed a long time until clots are formed and then to press the transplanted skin firmly on the part. Grafts of mucous membrane are disturbed by infection. For transplantation of ureter, the small intestine freed from serosa has been utilized. Grafting of fat is easily performed, while that of muscle and nerve is unsuccessful. Transplantation of vessels and of fascia has been quite success-

fully performed. The free grafting of tendon has resulted in the formation of a strong band in the resting condition, and in early motion in a structure that can functionate as a tendon. In the grafting of bone the best results are obtained with fresh bones covered with periosteum which have been removed from amputated limbs. Even bone removed from the dead is superior to dead bone. The transplantation of joints from amputated limbs or from the recent dead gives good results. A knee-joint that had been transplanted eight hours after its owner's death has healed into its new site five months later without a fistula. Entire extremities and organs have not yet been successfully transplanted.

Werner of Heidelberg has reported on the non-operative treatment of malignant growths. He has come to the conclusion that certain sarcomata and epithelial formations may be cured by means of radiation, toxins, and arsenic therapy; all other cases are best attacked surgically. Schumacher of Zurich described his experiments performed on animals and his two cases in human beings, in which by ligation of branches of the pulmonary artery he succeeded in causing atrophy of the diseased portion of the lung supplied by these branches. Similarly, Tregel of Dortmund, by using narrowing ligatures of silver thread, has caused venous hyperemia in the lungs and has been able to demonstrate that in these sections tuberculosis develops with great difficulty. Wilms of Heidelberg and Klose of Frankfurt discussed the subject of movable cecum. By fixation of the latter (cecopexy) they produced not only alleviation of the pain but also permanent cure of the chronic constipation.

At the seventh Congress of the German Röntgenological Society there was an extended symposium on the gastrointestinal canal. Kaufmann and Kienböck of Vienna brought *x*-ray pictures to demonstrate that foods do not mix in the stomach, but form layers. These pictures were obtained by giving individuals alternate portions of bismuth-containing and bismuth-free foods. Haudeck of Vienna described the distinguishing characterstics of ulcer and cancer. The ulcer is represented by its prominence in the picture, the cancer by its indistinctness. Other distinctions are associated wth the form of the stomach and the time taken for the expulsion of foods from the stomach. Günther of Bonn recommends barium sulphate as a cheap and non-toxic substitute for bismuth. A number of communications were presented as to whether the *x*-ray appearances of the hilum of the lung are to be attributed to the bronchi or to the vessels. No definite agreement was reached on this point. Albert Schönberg of Hamburg described the permanent therapeutic results of the *x*-rays in gynecology. Fibroids undergo considerable diminution in size, and the hemorrhages cease for good. These favorable results were even noticeable in climacteric hemorrhages as reported in the discussion. For epithelioma of the face Schmidt of Berlin recommends a combination of *x*-rays and mercury light. Grunmach of Berlin claims to have cured trigeminal neuralgia by means of *x*-ray treatment. Schulz of Berlin reported that he produced blanching of nevi without any reaction by means of the use of exceedingly mild rays. Plageman of Rostock has observed that staphylococci grow much better on culture media that have been exposed to the *x*-rays than on media that have not been so exposed. Even the garden soil exposed to the rays but once yielded a better growth from the seeds subsequently planted than neighboring soil not treated in this manner. In order to produce a better epilation of the skin, Bucky of Berlin resorted to a preliminary inunction with mercury. The epilation was thereby accelerated. A new glass for the manufacture of *x*-ray tubes has been known as the Lindemann glass. It consists of lithium, beryllium, and boron and absorbs about one-fifth as much of the rays as does ordinary glass.

At the tenth Congress of the German Orthopedic Society Stein of Wiesbaden reported his results with the use of diathermia, by means of which he succeeded in distinctly raising the temperature in the tissues. He utilized forms of apparatus that generate a high-frequency current with alternations of one million per second. The treatment is better than any other in acute gonorrheal arthritis. An acute attack of gout is always relieved by means of this measure, while chronic gouty and rheumatic articular changes are favorably influenced. Acute periostitis responds quickly to this method of treatment.

OUR VIENNA LETTER.

SCHOOL ANEMIA—PROGNOSTIC AND THERAPEUTIC SIGNIFICANCE OF UROCHROMOGEN IN PULMONARY TUBERCULOSIS—CLINICAL STUDIES ON HEART DISEASE.

VIENNA, July 1, 1911.

SCHOOL anemia and its prophylaxis was the subject of investigation by Medical Inspector J. Mendl, who examined the morphological condition of the blood in fifty school children. None of these had any complicating conditions, such as diabetes, nephritis, helminthiasis, etc. The changed relationships of the leucocytes and erythrocytes were found to be more of a qualitative than of a quantitative nature. There was neither a marked oligochromemia, nor a marked oligocythemia, nor was any difference to be noted in the sexes. The absolute count of the erythrocytes was markedly diminished in half of the cases, as a compensatory change there were small-celled poikilocytosis and increased pigmentary content. The anemia of school children is not an essential anemia, but is a pseudoanemia, with partly accountable and partly unaccountable causes. It affects not only the children of the poor, but also those of the well-to-do. In one-half of the cases there was a marked increase, amounting to as much as 25 per cent., in the eosinophiles. Substance in the school atmosphere that have a deleterious effect upon the blood of the children, have a positive chemotactic action for the acidophile cells, to which the child's organism reacts by means of an eosinophilia. This is a so-called toxic eosinophilia. A positive myelocytosis indicated a stimulation of the spinal cord by the school air, through the medium of the blood.

The significance of urochromogen in the prognosis and therapy of pulmonary tuberculosis was the subject of investigation by Moriz Weisz. The excretion of urochromogen has an unfavorable prognostic significance, being the result of a toxemia, occasioned by the toxins of the tubercle bacillus. In most cases this substance indicated an excess of toxins in the blood, taken up from lesions so extensive that cure is impossible. In other cases the excretion of urochromogen indicates a vulnerability of the organism to the tubercle bacillus, a condition that may be termed a predisposition. The protective mechanism of the body must therefore be associated in some way with the metabolism of urochromogen. This chemical process

is connected with the oxidative activity of the cellular protoplasm, in which one must perceive the chief weapon against the tubercle bacillus. The appearance of the excretion of urochromogen at the beginning of tuberculin treatment, and its later disappearance in the course of this treatment, show a gradual intoxication of the cells, due to a component of the tuberculin action. The appearance of urochromogen during tuberculin treatment indicates either that a particularly high tuberculin susceptibility exists, or that the chosen dose of tuberculin was too large.

The control of tuberculin therapy by means of urinary examinations can therefore serve to prevent the dangerous pushing of this treatment. A transient excretion of urochromogen is no contraindication to tuberculin therapy, but it emphasizes caution. In cases in which urochromogen is already being excreted in the urine, tuberculin treatment can hardly have any effect. The results of the penumothorax treatment is unilateral tuberculosis are better.

Clinical studies on heart disease have been reported by Privat Dozent D. Breuer. He notes that in various diseases of the heart the hypertrophy of the left auricle causes pressure of neighboring organs, such as the aorta, the esophagus, the bifurcation of the trachea, and the main bronchi. The greatest enlargement occurs in the left auricle, when it becomes hypertrophic and insufficient, as happens particularly in renal disease and arteriosclerosis, with the possibility of acute dilatation. Many cases of cardiac asthma depend upon such a paralysis of the left auricle. When enlarged this may press upon the bifurcation of the trachea, producing an obstinate cough. By pressure on the aortic arch the left recurrent laryngeal nerve may be compromised. Similarly, the esophagus may be pressed upon. The esophagus and the recurrent laryngeal nerve are seldom affected, however, unless they are immovably fixed, as by scars. Moreover, the esophagus is not very susceptible to stenosing action from without. The increased size of the left auricle may also cause cardiac orthopnea. Breuer believes that in the recumbent position the left auricle is pressed upon by the remainder of the heart; this occurrence is obviated by the sitting position or by some special attitude while lying down. Certain cardiac patients experience Cheyne-Stokes breathing, particularly during fatigue and during sleep. After a number of respirations there occurs a pause, lasting a half minute. Awaking occurs at the beginning of the respirations, and is associated with dyspnea, cyanosis, and dilatation of the pupils. In the period of respiratory pause the patients fall asleep again. Morphine cannot be used in these cases, for it is apt to bring on Cheyne-Stokes breathing. Effective remedies for the latter are a combination of atropine and morphine, and inhalation of oxygen; also, the inhalation of carbon dioxide is effective in stimulating the respiratory center.

Aerogenous Infection in Pulmonary Tuberculosis.—F. Gaertner maintains that in 90 per cent. of all cases the tubercle bacillus enters the body through the respiratory tract. Following the inhalation of tubercle bacilli, these are deposited on the walls of the pulmonary alveoli, which they irritate, with the resulting exudation of serum and the formation of tubercles. There is an early infection of the lymphatic glands at the hilum.—*Lancet-Clinic.*

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

SMALLPOX IN THE PROVINCE OF QUEBEC—ANNUAL REPORT UPON FEEBLE MINDED IN ONTARIO—PRIVATE HOSPITAL IN TORONTO—PROTECTION OF FOOD STUFFS IN TORONTO—DR. GEORGE ARMSTRONG APPOINTED TO ROYAL VICTORIA HOSPITAL, MONTREAL—FILTRATION PLANT FOR MONTREAL—CHOLERA ON BOARD SHIP—ACCIDENT TO DR. ANDREW MACPHAIL.

MONTREAL, July 24, 1911.

SMALLPOX has been present in epidemic form in the Province of Quebec for a period of eleven years. In November, 1899, the disease gained a foothold in the province, and each year since, especially during the winter and spring, appears in parts of Quebec. According to Dr. J. A. Beaudry, chief inspector of the Board of Health of Quebec province, one reason why the efforts put forth to stamp out the malady have not been crowned with success is because of the mild and somewhat abnormal form of the disease.

During the epidemic which has continued since November, 1899, smallpox in Quebec appears to have varied considerably from the classic type. The cases have been of a remarkably mild type, and have exhibited themselves in very variable forms. As said before, the type of the disease has been mild—so mild, indeed, that individuals affected, especially children, have not been confined to bed. Many of the children have amused themselves as usual, and the adults have followed their usual occupations and customs. The eruption has shown itself in an irregular manner, and in varied forms. In short, the disease has been of so modified a type that it has been frequently diagnosed as chicken pox and has been regarded so lightly that no special attention has been paid to it. Often medical men have not been called in, and even, sometimes, when their services have been made use of, they have not deemed the cases of sufficient gravity to notify the authorities, and the chief reason for its spread is that vaccination in the Province of Quebec, to a large extent, has fallen into disuse. Recently several cases of smallpox have occurred in Montreal which has attracted the notice of the public to the situation. The Board of Health, greatly hampered in its work by the apathy of the public, and in some instances by negligence of physicians to report cases, has seized the opportunity afforded by the cases in Montreal and the consequent fear of the community to institute a campaign against smallpox throughout the Province of Quebec. The following notice has been issued and distributed in all parts of the province:

"The Board of Health of the Province of Quebec, alarmed, and for cause, at the increasing spread of the epidemic of smallpox, not only in the Province of Quebec, but also in the whole of North America, and considering that consequently all municipalities of the province are actually threatened, and that vaccination is, in such circumstances, the only means that will save the province from the disasters which a generalized epidemic would mean, acting under the powers conferred upon it by the Quebec Public Health Act, orders each municipal council of the province to avail itself, within a period of five days from the date of reception of the present notice, of the powers conferred upon municipalities by said act and by Article 605 of the Municipal Code, and by virtue of such powers

to adopt, promulgate, and cause to be obeyed the following by-laws." These insist upon immediate vaccination where needful and advisable.

A considerable amount of opposition has been manifested in Montreal against the enforcement of compulsory vaccination, but Dr. Beaudry, with whom your correspondent had an interview, does not think that the objection is deep rooted. He ascribes the indifference of the people to taking measures for prevention to the fact that they have become so familiarized to smallpox by having the disease constantly in their midst that they have come to regard it as a matter of small importance.

Dr. Helen MacMurchy, in her fifth annual report upon the feeble minded in Ontario, thus sums up the situation so far as the school population is concerned in this respect. It is estimated that of about 600,000 school children .03 per cent. are feeble minded. In other words, about 1,000 feeble minded children are in the schools or of school age. In the opinion of Dr. MacMurchy these should be registered under the direction of the Education Department in order to be known and located. As for those remaining, the adults or those over school age should be reported to the Provincial Secretary's department. Those coming under the notice of the officers of the law should be tabulated in a similar manner. Finally, there should be a gradual development of this policy of care of the feeble minded in accordance with enlightened public opinion in the province. It has been announced recently that Drs. Bruce, Cavan, and other medical practitioners of Toronto have bought a large private residence in the city with a view of converting it into a private hospital. The house is commodious and well adapted for the purpose for which it is intended and is situated in about three acres of ground. A new wing is to be added with accommodation for sixty-six patients. Dr. J. U. E. Brown, who filled with success for several years the position of superintendent of the Toronto general hospital, has been appointed superintendent of this institution. There are also to be two house surgeons, together with an adequate staff of nurses. The Board of Health of Toronto has submitted to the Board of Control a by-law to protect food stuffs from contamination. The law is to the effect that all articles of food for sale are not to be conveyed from place to place or kept in an open window or doorway or outside a building unless covered with clean material; that every place where food is stored and sold shall be kept in a wholesome condition; that all persons engaged in handling articles of food shall wear clean outer garments; that any room in which articles of food are kept or sold shall not be used for domestic purposes; that the use of newspapers or unclean paper for wrapping articles of food is to be prohibited; that every vendor of food stuffs shall keep in his wagon a water-tight covered receptacle for the waste products of his business.

Dr. George Armstrong has been appointed surgeon to the Royal Victoria Hospital, Montreal, in place of the late Dr. James Bell. Dr. Armstrong has resigned from the staff of the Montreal General Hospital and will enter at once upon his new duties. Work on the new filtration plant for Montreal, to cost about $2,000,000, is in progress and it is thought that it will be completed in two years. Some cases of suspected cholera have occurred on a vessel bound to Montreal. The crew have been detained in quarantine at the quarantine station at Grosse Isle.

Dr. Andrew Macphail of Montreal, editor of the *Journal of the Canadian Medical Association*, some five weeks ago met with a somewhat serious accident. He was about to open a bottle of aerated water when the bottle exploded and pieces of glass cut his face and injured both eyes. Dr. Macphail has been treated in the Royal Victoria Hospital and has just left that institution for his country house on Prince Edward Island. It is stated that although one eye was badly injured his sight will not be affected permanently. Dr. Macphail is a writer of much versatility and is a man of great personal charm. His large number of friends in Canada and in Great Britain will hope that he may be soon able to resume his literary work with unabated vigor and undiminished power.

Soluble Silver Oxide. Its Use in Medicine. A Provisional Notice. T. W. Schaefer.
A Case of Syphilis Treated by Inunction of Mercury Related in the "Gesta Romanorum," which Was First Printed in 1473. C. M. Cobb.

Exploratory Diagnosis.—M. H. Richardson admits his strong inclination, under the restrictions of common sense, to the operative demonstration and diagnosis of suspected surgical diseases. He proposes the following conclusion: Operative investigation of suspected disease remediable only by mechanical or surgical means, when used by those fitted to make it, deserves the indorsement of physicians as well as of surgeons. Before resorting to the exploratory operation all reasonable means of diagnosis should be exhausted, except in cases of emergency from obscure causes in which the necessity for mechanical remedy is self-evident. In tumors of uncertain nature, especially those associated with areas or organs subject to malignant disease, and especially at the cancer age, exploratory demonstration of the tumor and, if necessary and possible, microscopic determination of its nature should, in the absence of contraindications, be the rule. In the multiplication of indications for mechanical and operative treatment, surgery has become a highly specialized art and broad science, for the practice of which special preparation is essential. For the practice of surgery, the study of the morbid anatomy of surgical diseases in the living as well as in the dead, and its relation of symptoms, especially those diseases producing mechanical symptoms, should be, with the study of normal anatomy, the surgeon's chief endeavor. Finally, the exploratory diagnosis should be restricted in its application in those cases in which certainty of diagnosis is essential to relief, and in which, from lack of surgical remedy, error means disaster or death.

Tuberculosis.—V. Y. Bowditch sums up his attitude toward the question of the final eradication of tuberculosis in the following way: He has had a faith for years and still feels that one may be on the eve of some brilliant discovery of a method which shall be a greater aid in one's work than anything thus far adopted. That we are moving in the right direction and have already accomplished much he is firmly convinced. While he cannot share the optimism of those who believe that in a generation, by the general extension of present methods, one will find tuberculosis under complete control, yet he believes that at the end of that time vast progress will have been made toward the desired result.

Mobilization of Stiffened Joints.—R. B. Osgood reports three cases in which is shown the possibility of preventing reunion of bone in cases of complete bony ankylosis. In the cases reported the membrane of Baer, of Johns Hopkins, was used to prevent union. This is a tough membrane obtained from the bladder of the pig, sterilized and chromicized like catgut, and supposed to remain in the body tissues without being absorbed for at least thirty days.

Clinical Tests for Apraxia.—I. H. Coriat presents an outline of some clinical tests for motor apraxia, and indicates their value in the diagnosis of organic diseases of the brain. Motor apraxia occurs in lesions of certain portions of the brain, particularly of the corpus callosum and of the left parietal lobe, as a result of which the sensorimotor zone is cut off from communication with the temporal and occipital lobes. The following varieties of apraxia are to be distinguished from one another: eupraxia, the intactness of reproduction of coordinated movements; apraxia, complete lack of reproduction of coordinated movements; dyspraxia, partial lack of reproduction of coordinated movements; motor apraxia, an inability to make movements or to use objects for the purpose demanded by the will; ideational apraxia (or agnosia), a misuse of objects due to a disturbance of identification.

Soluble Silver Oxide.—T. W. Schaefer states that this is a soluble preparation of silver, entirely free from an acid radical, and therefore eminently available for the various therapeutic uses of silver.

Mercury in Syphilis.—C. M. Cobb cites a fable from the "Gesta Romanorum" of 1473, which contains a veiled allusion to the treatment of syphilis with the aid of mercury.

New York Medical Journal.

July 22, 1911.

The New York Academy of Medicine. C. L. Wheeler.
The Laboratory Findings in Neurological Manifestations. D. M. Kaplan.
Fracture of the Anteroexternal Portion of the Lower Condyle of the Tibia, Complicating Pott's Fracture. M. Leale.
Some Medical Gossip Pertaining to the Last Illness of Queen Anne of England. C. G. Cumston.
Early Diagnosis of Cancer of the Breast. A. E. Isaacs.
Papular Eruptions of the Buccal Mucous Membrane. H. K. Gaskill.
The Etiology, Prophylaxis and Treatment of Postanesthetic Vomiting. J. Halperin.
Some Remarks on an Operation for Progressive Spinal Deformities in the *New York Medical Journal* for May 27, 1911. W. G. Elmer.

The New York Academy of Medicine.—C. L. Wheeler presents a short history and description of the present home of this organization.

Laboratory Findings in Neurology.—D. M. Kaplan concludes that the Wassermann reaction is only an etiological indicator, and in neurology its presence cannot always serve as a therapeutic guide. The serologist's technique should be inquired into. Cerebrospinal syphilis and general paresis cannot be differentiated, using the finding of Plaut as a working basis. The cytology is the most important element in the pathology of the cerebrospinal fluid. No meningitis ought to be excluded or established without a cerebrospinal fluid analysis. Multinucleosis and the absence of the Fehling reducing substance go hand in hand and are significant of an acute process. The ring test for the detection of an excess of protein in the cerebrospinal fluid gives an approximate quantitative insight into the degree of increase.

Fracture of Lower Condyle of Tibia.—M. Leale reports a rare case of fracture of the anteroexternal portion of the lower condyle of the tibia, complicating Pott's fracture.

Last Illness of Queen Anne.—C. G. Cumston reviews certain documents relating to the last illness of Queen Anne of England.

Cancer of the Breast.—A. E. Isaacs states that pain is an inconstant symptom, especially in the early stages. Limitation of mobility of the breast is an important sign. Raising of the level of the nipple on the affected side is an early sign of value. Retraction of the nipple comes later. Discharge from the nipple, when cloudy or bloody, is always suspicious. The more pronounced evidences, such as glandular involvement, metastasis, adhesion of the tumor to the chest wall, or puckering of the skin, are comparatively late signs.

Papular Eruptions of Buccal Mucous Membrane.—H. K. Gaskill states that the most common of the papular eruptions that resemble at certain stages of their development Koplik's spots are Fordyce's disease, aphthous stomatitis, lichen planus, mucous patches, sprue, and thrush.

Postanesthetic Vomiting.—J. Halperin states that the best method of combating postanesthetic vomiting is to keep the patient motionless in a quiet room and to administer small quantities of hot water or cracked ice at frequent intervals.

Spinal Deformities.—W. G. Elmer advances arguments in opposition to the performance of an operation for ankylosing the affected vertebræ in tuberculosis of the spine, and to the performance of arthrodesis of the spine in lateral curvature.

Journal of the American Medical Association.

Animal Experimentation in Relation to Epidemic Cerebrospinal Meningitis. C. H. Dunn.
The Optometry Question and the Larger Issue Behind It. E. Jackson.
Serous Labyrinthitis. J. R. Fletcher.
Tuberculous Cyclitis Following Non-Perforating Injury to the Eye. O. Dodd and F. Lane.
Plastic Surgery of the Eyelids Using the Wolffe Graft. F. P. Calhoun.
A Case of Acute Gastric Ulcer of the Anterior Wall. A. Bassler.
Fracture of the Cervical Spine. T. M. Williams.
Anaphylaxis and the Toxic Substance from Virulent Pneumococci. E. C. Rosenow.
Emphysema of the Skin Occurring During Labor. M. J. Siegelstein.
Removal of an Open Safety-Pin from the Trachea by Upper Bronchoscopy. G. Hudson-Makuen.
Studies on Pyocyaneus Immunity with Special Reference to the Therapeutic Value of Vaccines. N. Gildersleeve.
A Case of Raynaud's Disease. G. B. Lemmon.

Animal Experimentation and Cerebrospinal Meningitis.—C. H. Dunn discusses the history of the experimentation that led up to the production of the antimeningococcic serum, and the favorable manner in which the latter has influenced the mortality of epidemic cerebrospinal meningitis.

The Optometry Question.—E. Jackson discusses the fallacies of the arguments advanced by the optometrists.

Serous Labyrinthitis.—J. R. Fletcher states that this condition should be recognized as one of the inflammatory diseases of the labyrinth.

Tuberculous Cyclitis.—O. Dodd and F. Lane report a case of this condition following a non-perforating injury to the eyeball—the result of the patient being struck with a baseball ten months before.

Plastic Surgery of Eyelids.—F. P. Calhoun recommends the Wolffe deep cutaneous graft as the ideal one to be employed in restoration of the lids and the cul-de-sacs in complete ectropion of the eyelids.

Gastric Ulcer.—A. Bassler reports a case of gastric ulcer of the anterior wall—an uncommon condition.

Fracture of Cervical Spine.—T. M. Williams presents the history of a case of fracture of the fourth and fifth cervical vertebræ.

Anaphylaxis and Pneumococci.—E. C. Rosenow reports the results of his experiments on the anaphylotoxic substance obtained by the interaction of pneumococci, immune serum, and normal serum.

Cutaneous Emphysema During Labor.—M. J. Siegelstein reports a case of this condition.

Removal of Open Safety-Pin from Trachea.—G. Hudson-Makuen reports the successful removal of an open safety-pin from the trachea of a young girl by means of bronchoscopy.

Pyocyaneus Immunity.—N. Gildersleeve concludes that a marked increase in both the opsonic and agglutinative elements can be induced in the animal economy by the injection of vaccine as well as the living organisms. Therefore, the employment of vaccine in the treatment of local pyocyaneus infections would appear to be rational. However, there is also a toxin produced by the organisms under consideration, the action of which manifestly cannot be counteracted by the use of vaccine. Should one decide to employ vaccine in treating these infections, such vaccine must be prepared from the organism concerned in the individual infection under treatment, and never from strains that have been cultivated on artificial media for a number of generations. These organisms soon lose their virulence under artificial cultivation and at the same time, at least to a great extent, their power of conferring immunity.

Raynaud's Disease.—G. B. Lemmon reports a fatal case of this condition, in which there was a strong hysterical element.

The Lancet.

July 15, 1911.

A Clinical Study of Cardiovascular Degeneration. J. Bruce.
The Treatment of Phthisis and Hemoptysis by Artificial Pneumothorax. C. Lillingston.
Notes on Four Cases of Phthisis in which Artificial Pneumothorax Was Induced. L. Colebrook.
A Case of Artificial Pneumothorax Produced in Treating Chronic Pulmonary Tuberculosis. S. A. Pearson, A. de W. Snowden, and C. Lillingston.
A Case of Torsion of the Pedicle of a Uterine Fibroid. C. A. Morton.
A Case of Acute Inammation of the Thyroid Gland. C. W. Bonney.

Cardiovascular Degeneration.—J. M. Bruce states that disorders of nutrition are included among the causes of cardiovascular degeneration. One of the most important of the former is intermittent glycosuria. The subjects of degeneration of the heart and arteries associated with glycosuria suffer from all the ordinary symptoms of cardiac disability and distress. As to the physical signs, the aortic diastolic murmur which figures so largely in syphilis is never found, but in many of these cases an apical systolic murmur is present. The clinical course is unusually slow. In the author's 100 cases of cardiovascular degeneration gout was the important etiological factor in 44. In most of these cases the heart is enlarged, with a normal or increased impulse, an aortic systolic murmur, and an apical systolic murmur. A small proportion of cases of cardiac enlargement, with or without arterial sclerosis, may be traced to physical strain in early manhood. There is another group of cases in which the relation of physical stress to the nutritional condition of the cardiovascular walls is the reverse: where the original stress falls upon a middle-aged or old heart already unsound.

Treatment of Phthisis and Hemoptysis by Artificial Pneumothorax.—C. Lillingston states that Forlanini's plan of introducing nitrogen between the two layers of the pleura through a fine, hollow needle, and thus inducing collapse of the lung, can now be carried out with ease in cases uncomplicated by adhesions, provided the operator carefully carries out every detail of the recently improved technique.

Phthisis and Artificial Pneumothorax.—L. Colebrook reports four cases of pulmonary tuberculosis in which artificial pneumothorax was induced. These were all very grave cases, and in two of them the rest afforded to the lung marked a turning point in the infection. The author concludes that the method is worthy of serious attention.

Artificial Pneumothorax.—S. V. Pearson, A. de W. Snowden, and C. Lillingston report two cases in which artificial pneumothorax was induced in the treatment of chronic pulmonary tuberculosis. In one of these cases the success of the treatment was striking; in the other case the treatment was a failure.

Torsion of Pedicle of Uterine Fibroid.—C. A. Morton reports a case of this condition, noting its extreme rarity.

Acute Inflammation of the Thyroid Gland.—C. W. Bonney reports the case of a small patient who had had a goiter for 16 years, and in whom, following an attack of pneumonia, the goiter increased greatly in size. As the result of this the patient suffered greatly from dyspnea, pain, and progressive deterioration of health. At operation it was found that the entire left lobe of the thyroid had become converted into an abscess cavity.

Some Notes on the Absorption of Iron. D. G. McL. Munro.
Treatment of Pulmonary Tuberculosis by Means of Carbolic Acid Injections. H. Vallow.
A Report on Fifty Cases of Trachoma Treated with Carbon Dioxide Snow. G. M. Harston.
Administration of Serum by the Mouth. G. I. Cumberlege.
Intrathyroid Hemorrhage Followed by Acute Dyspnea and Death. S. G. Champion and C. B. M. Aldridge.
The Discrimination of Color. F. W. Edridge-Green.
Menorrhagia in Virgins: A Medicinal Treatment. F. Hare.

Cardiac Failure Without Cardiac Dilatation.—T. S. Wilson reports three cases of muscular failure of the heart without marked enlargement and without valvular disease. The first case showed heart weakness with diminution in the size of the cardiac area from damage to the heart muscle from the toxins or microorganisms of acute rheumatism. In this case the left ventricle was rather weaker than the right, and the latter showed a slight amount of the adolescent type of dilatation and a pulmonary artery murmur. The second case was one of the muscular failure of the heart, without evident dilatation, due to malnutrition presumably from atheroma of the coronary arteries. In this case the left ventricle was more affected than the right. The third case was exceptionally interesting owing to the limitation of the fatty degeneration to the right ventricle as well as from the absence of physical signs of cardiac failure except those associated with a relative emptiness of the heart and great vessels, and the weakness of the cardiac sounds, especially those heard over the right ventricle.

Endoaneurysmorrhaphy.—A. E. Barker reports a case of popliteal aneurysm treated by means of the method elaborated by Matas—obliterative endoaneurysmorrhaphy. The results in this case were good.

Anthrax Treated by Sclavo's Serum.—W. M. Fergusson reports a case of anthrax treated by Sclavo's serum, in which recovery took place without excision of the pustule. Most cases of recovery after treatment by Sclavo's serum have been treated by excision as well.

Antimony in Trypanosomiasis.—C. N. B. Camac reports a case of trypanosomiasis in which intramuscular and intravenous injections of antimony were used. For over two years prior to the treatment there had been twenty-six febrile paroxysms associated invariably with trypanosomes in the peripheral blood. Following the treatment, except for two rises of temperature that occurred with the other symptoms of poisoning, no fevers have occurred and the trypanosomes have not been found in the peripheral blood or in animals inoculated with blood and spinal fluid.

Treatment of Serum Sickness.—J. R. Keith reports a case of serum sickness following the use of antitoxin in diphtheria. Calcium lactate administered in one of these cases caused the disappearance of the rash, but no other effect was seen. The salicylates produced more satisfactory results.

Absorption of Iron.—D. G. McL. Munro reports the results of his experiments, in which it would appear that iron in organic combination with vegetable albumin has an advantage over Blaud's pill or ammonicitrate of iron.

Carbolic Acid Injections in Pulmonary Tuberculosis.—H. Vallow reports three cases in which this treatment was followed by good results. The method employed was the injection once a week of 0.1 to 0.2 c.c. of a 1 per cent. solution of pure carbolic acid in distilled water. The improvement, which was most marked in the early cases, consisted in regular increase in weight, improvement in appetite, and diminution and even disappearance of physical signs.

Carbon Dioxide Snow in Trachoma.—G. M. Harston reports the successful treatment of 50 cases of trachoma by means of carbon dioxide snow.

Diphtheria Antitoxin Administered by the Mouth.—G. I. Cumberlege advocates this method of administration, claiming good results in his own experience, without any of the disadvantages associated with the hypodermic administration.

Intrathyroid Hemorrhage.—S. G. Champion and C. B. M. Aldridge report the case of a domestic, aged 24, who, following a fall from a car, soon gave signs of collapse and severe dyspnea, and died an hour and a half after the accident. At autopsy the thyroid, which was goitrous, was found to be the seat of a large hemorrhagic cyst.

Discrimination of Color.—F. W. Edridge-Green states that when special means are taken to have as pure a spectrum as possible he can find no method which will enable him to distinguish as separate colors the wave lengths in a monochromatic region.

Menorrhagia in Virgins.—F. Hare states that excessive menstruation may depend upon exaggerated vascular tone. For this reason he finds justification for the use of amyl nitrite, the inhalation of which even in single administrations of 3 minims has been sufficient to effect permanent relief from the tendency to excessive losses.

July 10, 1911

Syphilitic Reinfection or Pseudochancre?—Gutmann brings this subject up in connection with the recent advances in the diagnosis and treatment of syphilis. He is inclined to think that in the main both "superinfection" and "reinfection" represent secondary manifestations. He does not refer in this paper to the chancre redux or recrudescence of the disease in the scar of a former chancre. The nature of this accident is well known, and it should never be taken for a lesion of reinfection. The author appears to believe that most of the alleged reinfection chancres have no sounder status. Two cases are given in which about a year after a chancre had first developed and had been found to contain spirochetes, and had been duly treated until the Wassermann became negative, second "chancres" had appeared. In one instance the second chancre was close to the site of the first, but in the other it appeared in the urethra. In the interim the patients had been thoroughly mercurialized. The question of a second exposure to contagion is not touched on. The second chancres were solitary manifestations, as is usually the case with so-called chancre redux. The Wassermann was still negative. Such lesions are by no means unknown, even without reference to the question of second infection; for in 1907 Thalmann described a solitary secondary lesion which was able to set up local adenopathy, and even at times a roseola. It is possible that such lesions develop only after thorough mercurialization. The organism being thereby largely freed from spirochetes, a local depot of the latter might later become actuated and simulate reinfection. The negative Wassermann would appear to document such a theory. It is, of course, understood that this line of argument applies solely to alleged recent reinfection. Of a wholly different character are cases of supposed reinfection many years after the primary infection. After five years' interval at the very outside—far less in actual practice—no secondary manifestation could occur without a revolution in our nomenclature. From this point of view, *i.e.* reinfection of recent date, the author is inclined to be very skeptical as to all reported cases. The burden of proof of reinfection lies upon the writer who reports such cases; and if it is admitted, as it must be, that these pseudochancres which answer all tests for chancre may develop within the first year or two, it will be very difficult to prove that reinfection ever occurs in such interval. The question can only be decided by experiments on human volunteers.

Syphilitic Anterior Poliomyelitis in Adults.—Zadik takes up this subject, which becomes of much interest when we reflect that the epidemic type of the Heine-Medin syndrome is now known to attack adults. Goldflam was the first to record the syphilitic type, in 1893. The condition developed in the early secondary period, and was cured with Hg; hence it could not in all likelihood be classed as metasyphilitic, but as a variety of syphilitic myelitis. Nonne reports three cases which recovered under mercury, while two patients of Hoffmann did not make complete recoveries, the matter of treatment being ignored by the writer. Zadik now quotes two personal cases which bring the total number to eight. The successful use of mercurials in treating his patients not only suffices to clinch the diagnosis of luetic poliomyelitis, but it further shows decidedly that this location of disease in the anterior columns of the cord possesses not the remotest relationship to tabes dorsalis.

Specific Tuberculosis Therapy.—Wolff-Eisner concludes a serial article on this subject as follows: Tuberculin artificially prepared has the same action on the organism as the tuberculin absorbed from specific lesions. The parallelism is complete from all sides, including the fluctuations of the opsonic index. Different tuberculins have been prepared, but a nontoxic product has thus far defied isolation. The different activities of tuberculin do not rest on different components, but on a polymorphic activity of tuberculin itself. The latter is not a "toxin" in the commonly accepted sense of that term. It is a poisonous albumin, akin to endotoxins. It is not a toxin because it does not generate an antitoxin, *i.e.* a neutralizing antibody. It does bring about the formation of a lysin, and only after uniting with the latter does it become toxic. The nonappearance of a tuberculin reaction after tuberculin treatment means perhaps that the foreign tuberculin has united with reactionary receptors. From the practical side all writers agree that tuberculin should be exhibited in minute doses so that a reaction will not be provoked. This, however, does not necessarily exclude the fact that sometimes a reaction is demanded. There is a reactionless and a reactionary therapy. The former is requisite in dispensary cases, at least. Four weeks should elapse between injections. Falyvalent tuberculin—or a combination of the old and new—should be employed. In treating typical consumption the vaccine therapy should reinforce the specific treatment, and a mixed or polyvalent vaccine should be employed containing strepto-, staphylo-, and pneumococci. The chief immediate dangers to the tuberculous subject come from superinfection.

Prevention of Adherent Pericardium.—Alexander has found that adhesion of the two layers of the pericardium that usually follows pericarditis may be prevented by the introduction of sterile air into the pericardial sac, which serves in a simple and harmless manner to keep the two serous surfaces apart until the inflammatory process has run its course.—*Zeitschrift für physikalische und diätetische Therapie.*

Insurance Medicine.

Hospitals in Great Britain and the Proposed National Insurance Bill.—(See page 281.)

American Association of Medical Examiners.—(See page 306.)

Appendicitis in Relation to Life Insurance.—John Fawcett does not altogether agree with the condition laid down by an American office that an applicant must have been free from an attack of appendicitis for a period of two years ere his application would be considered. Several medical authorities take a similar view. The author makes the following points: (1) The risk of a second attack of appendicitis occurring is a diminishing one. (2) For practical purposes some limit of time must be fixed at which the risk reaches zero, and for that purpose a period of five years is suggested from the termination of the first attack. (3) Some additional rate must be fixed to the premium to cover the risk for these five years. (4) Whatever the rate fixed may be, in the case of an applicant who is going abroad or who will be out of the reach of skilled assistance at least double the fixed rate should be charged. Fawcett proposes to tax those cases in which appendicitis has occurred by an addition to the premium for a period of five years of 1 per cent. on the sum assured. This is thought to be a better plan than to create a debt on the policy; first, the insurer gains thereby the full value of his policy for a comparatively small extra cost considering the risk the company is taking; secondly, there is no dissatisfaction on the part of the beneficiaries, as there would be if after the death of the insured in the first year or two they found they were entitled to only half or three-fourths of the sum for which the deceased was insured on account of the debt on the policy.

In the case of relapsing appendicitis the author suggests postponing the application until after the vermiform appendix has been removed, or else the determination of a rate to cover the risk of operation. Fawcett thinks such a rate might be recommended as would cover a possible claim of 2 per cent. of all cases in which the vermiform appendix is removed during the quiescent period, and this would be met by a single addition of 2 per cent. on the sum assured.

In the case of an applicant accepting the terms but not undergoing an operation and dying from appendicitis within twelve months Fawcett is of the opinion that the risk of such an attack is so exceedingly small that the company might accept it. In the case of a proposer who at the end of a year, when about to pay his second premium, was found not to have submitted to operation, it is suggested that 2 per cent. be added each year to the premium for the first five years and 1 per cent. for the next five years, unless, in the meantime, a certificate shall have been received that the vermiform appendix had been successfully and completely removed, when no further extra premium would be required.

In the case in which an abscess has been opened and the appendix not removed, if the operation wound has healed and tht applicant appears in all ways sound, acceptance might be reasonably granted three months after operation with an addition of 1 per cent. on the sum assured for two years. Twelve months after the operation risks might be taken with 1 per cent. on the sum assured for one year. After eighteen months to two years from the time of complete recovery from the operation ordinary rates may be charged. In case of appendicular abscess in which the appendix was removed at the time of the operation, if all is satisfactory at the end of three months, the applicant might be accepted with an extra 1 per cent. on the sum assured for one year, and after a year has passed at ordinary rates. In a case of appendicular abscess ruptured spontaneously and not operated upon, no applicant, even in the simplest case, should be accepted until at least six months after complete disappearance of all signs and symptoms of appendicitis or its results. After that an addition of 1½ per cent. on the sum assured for the next two years would be a reasonable one to make to cover the risk involved.

Cases of general peritonitis (*a*) with or (*b*) without a localized abscess and removal of the appendix: (*a*) No cases should be accepted at an earlier period than twelve months after the operation wound has soundly healed. If the case is one in which simple drainage has been carried out and the appendix has not been removed, then some such addition as 1½ per cent. might be charged for two years and no case accepted earlier than twelve months from date of operation. (*b*) In severe cases at least two to three years' immunity from symptoms should be required before acceptance is considered, and for the next two or three years, at any rate, some addition would be necessary to cover the risk—possibly 1 per cent. on the sum assured for the period mentioned might suffice.—*Transactions of the Life Assurance Medical Officers' Association, London, for 1908 and 1909.*

The Work of the Census in Vital Statistics.—Cressy L. Wilbur, chief statistician of the United States Census Bureau of Vital Statistics, read a paper with this title at the fourth annual meeting of the Association of Life Insurance Presidents held in Chicago. He stated that life insurance is a commodity, the value and chief cost of which depend primarily upon the risk of dying, and its derived function, the expectation of life. These can be measured only by a correct mortality table, or as it may be preferably called for general statistical and sanitary purposes, a life table. Sanitation is likewise a commodity even more necessary and important than life insurance. Knowledge as to the prevention of disease and disability and the prolongation of life, which is absolutely necessary for modern scientific public health work, cannot be acquired without the aid of accurate vital statistics. Yet the United States is far behind other leading countries in the registration of deaths, and even more so in the registration of births. According to data secured by the French Government for its international tables, China, Turkey, and the United States cannot present any statistics of infant mortality because they do not register their births and deaths. Japan is now fifty years ahead of the United States in the registration of vital statistics. This country does not possess even fairly accurate registration of deaths for much more than one-half of the total population (55.3 per cent.), and there is practically no complete registration of births for even a single State or a single city in the entire Union. Boston, which claims to have the best system of registration of births among the cities of this country, records only about 96 per cent. of those that occur. The worst form of birth registration may be found in Baltimore, Chicago, and New Orleans. Model laws for securing better vital statistics have been drafted and have been endorsed by the Bureau of the Census, the American Public Health Association, and the American Medical Association. Since the census was placed on a permanent basis, the area of registration for deaths has been extended. To the ten States that constituted the registration States in 1900, namely the six New England States, New York, New Jersey, Indiana, and Michigan, there were added, for 1906, California, Colorado, Maryland, Pennsylvania, and South Dakota; for 1908, Washington and Wisconsin; and for 1909, Ohio. On February 1, 1910, the model law went into effect in the State of Missouri. Kentucky began with its new law on January 1, 1911. The South, except for certain registration cities, now stands nearly unrepresented in the national vital statistics. The present system in Illinois is worthless and it is hoped will soon be discarded. Even in States which possess laws for the satisfactory registration of births, no systematic effort is made to *enforce* these laws, with the exception of Pennsylvania, Ohio, and Missouri.

in which are being made the first determined efforts ever made in the United States to enforce thorough registration of births on a State wide basis and under State law. Pennsylvania is the pioneer in this respect. State and city boards of health that undertake to carry on their work without reliable vital statistics are blindly working in the dark. The foremost work done by the census in vital statistics is that for the extension of the registration area and the adoption and thorough enforcement of good registration laws for births and deaths. The foundations for this work should be laid square and strong, and one should not be too anxious to gain some temporary advantage in adopting principles that will prove disastrous in practice. One of these is the compensation of physicians and midwives for reporting births, and even of physicians for reporting deaths, as is the law of Illinois at present. Money expended for this purpose is not only unnecessary, but serves as an actual detriment to complete registration. Legislators should not be given occasion to impugn the motives of the medical profession in regard to proposed legislation for better vital statistics by any suggestion of "medical graft." The system which attempts to collect or transmit registration returns of births and deaths through the agency of some county official is worthless. The county official is simply a middleman, a fifth wheel that interferes with the direct control that should exist between the State registrar and the local registrars. The standardizing of registration returns and published data can be accomplished by the use of the United States Standard Certificate of Death, and the corresponding certificate of birth. The standard death certificate which went into effect January 1, 1910, contains provision for the more precise statement of age of infants dying very soon after birth, thus enabling one to make a sharp distinction necessary between still births and deaths of children born alive; the more definite statement of both industry and specific occupation of decedents, and uniform instructions for the proper statement of occupation and cause of death. The international system of classification as adopted by the census has been largely instrumental in securing its general acceptance. The precise statement of occupation is of great importance; in the new standard certificate there is to be stated not only the trade, profession, or particular kind of work, but also the general nature of industry, business, or establishment in which employed. The subject of uniform tables for use in federal, State, and municipal reports and bulletins upon vital statistics is now under consideration. The aid of the life insurance companies is invoked to hasten the time when accurate vital statistics will be had for the entire United States. Life insurance, like sanitation, is crippled by the lack of vital statistics. To-day many parts of the South are misrepresented and discriminated against because of the fact that in these regions no accurate vital statistics are available. Companies fear to enter certain States and higher rates are charged to persons insuring. The person insured has by far the greatest interest in knowing the exact conditions of mortality upon which his rates are or should be based. The Bureau of the Census publishes annually a report and a bulletin on mortality statistics, and contemplates the publication of special volumes with "corrected" death rates, a special report on occupational mortality, and a volume on Life Tables, the last with the aid and advice of the Actuarial Society of America. It is important that every life insurance company, its president, general officers, district representatives, agents, and policy holders, should demand full information upon the vital statistics of the United States and should urge the adoption and thorough enforcement of laws for this purpose.—*Proceedings of the Fourth Annual Meeting of the Association of Life Insurance Presidents*, December 9 and 10, 1910.

Early Gout in Two Fatal Cases.—An applicant for life insurance gave the history of a "rheumatic" inflammation of the midjoint of the foot which was treated by massage and baths. His family history was good. Physical examination showed an excess of "panniculus adiposus" in a rather small-statured man. The medical examination recommended him for insurance, explaining the inflammation of the joint by the existence of a flat foot. The medical director, however, pointed out that this affection would compel the applicant to choose a sedentary occupation and thus favor further increase in adiposity. He was therefore insured not for life, but until sixty-five years of age. Two years later he renewed his application for life insurance, the medical examiner having changed his diagnosis to gout instead of flat foot as the cause of the joint trouble. In the interval he had gained further in weight. This time the medical director recommended that fifty-five years of age should be the terminal limit of insurance. He was thirty-two years old at the time of the first application. The prognosis of the medical director proved to be even too favorable, the patient dying of chronic myocarditis at forty-nine years of age. Another applicant was thirty-one years old and gave a history of a gouty attack two years previously. The medical examiner described it as a very light case of gout and the medical director, though with some misgivings, recommended insurance for life. Six years later the applicant applied for a second policy. In the interval he had more attacks of gout, one brother became likewise affected and the applicant's mother was also subject to gout. The medical director recommended refusal of reinsurance, but finally compromised on fifty-five years as the limit of insurance because of the warm recommendation of the examining physician. The applicant refused this compromise. He died at fifty-nine years of age from a cerebral hemorrhage in consequence of gout and accompanying arteriosclerosis.—*Blätter für Vertrauensärzte der Lebensversicherung*, January and February, 1910.

Significance of an Acute Costosternal Angle.—Ebstein, writing in the *Münchener medizinische Wochenschrift*, 1909, No. 46, concludes that a well-marked angle at the articulation of the second rib with the sternum has some relation to a growing aneurysm of the aorta. Otherwise its pathognomonic significance is *nil*, neither pulmonary tuberculosis with consequent emphysema nor rickets having anything to do with its appearance. A prominent articulation between the manubrium and the body of the sternum (angle of Louis) has no greater significance, though certain authors have tried to show its relation to pulmonary tuberculosis.—*Blätter für Vertrauensarzte der Lebensversicherung*, January and February, 1910.

Claim Under Workman's Compensation Act.—A judgment was recently given by the Recorder of Dublin in a case in which compensation was claimed under the workman's compensation act by the widow of a deceased workman, who had been employed loading a wagon, and had just carried a bag weighing 224 pounds and thrown it into the wagon, when he fell dead. The post-mortem examination showed the existence of advanced valvular disease of the heart. The Recorder held that the work in which deceased had been engaged contributed to his death and awarded $750 compensation.

Mortality of Hand-Fed Infants.—Mr. Frederick S. Crum, statistician for the Prudential Life Insurance Company, furnishes statistics showing the comparative death-rates among hand-reared and breast-fed infants. He says that in Hull, England, it was found that in their third quarter of the year, during a five-year period, there were 991 deaths from diarrhea of infants fed on a mixed diet, as against only 190 deaths from the same cause of infants entirely breast fed. The Berlin statistics for a number of years show the definite relation of hot weather and method of feeding to infant mortality. Invariably the death-rates of both classes of infants go up above normal during the hot weather, but the increase in mortality among the artificially fed is greater—out of all due proportion—than the increase in the mortality of the breast fed.

Book Reviews.

Case Histories in Pediatrics. A collection of histories of actual patients selected to illustrate the diagnosis, prognosis, and treatment of the most important diseases of infancy and childhood. By John Lovett Morse, A.M., M.D., Assistant Professor of Pediatrics, Harvard Medical School, Associate Visiting Physician at the Infants' Hospital, and at the Children's Hospital, Boston. Price, $3.00. Boston: W. M. Leonard, 1911.

The title page of this book amply indicates its purpose and scope. If one has not yet gauged the value of the method of case teaching which has been introduced into the Harvard Medical School, then a perusal of this book will dispel any doubt as to the efficiency of this didactic method. One need only recall the memories of one's own student days to realize the fact that clinical lectures are largely commensurate with the teaching skill and not necessarily with the knowledge of the lecturer. The wise teacher utilizes the case as a means of developing the diagnostic powers of his pupils. Dr. Morse has succeeded in combining with an extensive knowledge of his subject matter this correct psychological method of presenting it. The practitioner will find between the covers of this book a real pediatric clinic in which all the common ailments of childhood are presented in the order commonly observed in text books on pediatrics. A book like this is obviously far from being thorough, but it has the advantage of being concise and concrete. Altogether one hundred case histories are presented. Their diagnosis is given in detail, with the various points in different diagnosis. The treatment of each case is given with a due regard for therapeutic details that are generally lacking in most text books. The latest advances in pediatric science are mirrored in the pages of this book which will prove valuable to the postgraduate no less than to the undergraduate student.

A Practical Medical Dictionary of Words Used in Medicine. With Their Derivation and Pronunciation, Including Dental, Veterinary, Chemical, Botanical, Electrical, Life Insurance, and Other Special Terms; Anatomical Tables of the Titles in General Use and Those Sanctioned by the Basle Anatomical Convention; Pharmaceutical Preparations, Official in the U. S. and British Pharmacopœias and Contained in the National Formulary; Chemical and Therapeutic Information as to Mineral Springs of America and Europe, and Comprehensive Lists of Synonyms. By Thomas Lathrop Stedman, A.M., M.D., Editor of "Twentieth Century Practice of Medicine"; Editor of the Medical Record. Illustrated. Price, thumb indexed, $5.00; plain, $4.50. New York: William Wood & Company, 1911.

This new dictionary, of over 1,000 pages, gives the derivation of all words when known. Pronunciation is indicated whenever it is not self-evident, and accent is marked in all the main titles and in most of the subtitles. Tables of the anatomical structures, such as arteries, muscles, nerves, sulci, convolutions, foramina, fossæ, and pharmaceutical preparations, such as acids, tinctures, etc., are run along in columns in alphabetical order, distinguished by different type. Other tables, such as of the elements with their symbols and atomic weights, thermometer scales, weights and measures, etc., are placed in the Appendix. Besides the regular medical terms this dictionary includes: dental, chemical, veterinary, botanical, insurance, homeopathic, and eclectic terms; and biographical data (nationality, date of birth, and death) with the eponymic terms. All the [BNA] terms are indicated. All the preparations of the United States and British Pharmacopœias and National Formulary are included. Chemical symbols are given with the names of acids, salts, etc., and also entered as main titles referring back to the full name. The work also includes mineral springs, giving pronunciation of place (if foreign), country, character of the water, and indications for its use; and a thesaurus feature, that is, defining back from the English or popular terms to the scientific. Words which should begin with a capital are so printed. The spelling of the U.S.P. is used.

The House Fly, Disease Carrier.—An Account of Its Dangerous Activities and of the Means of Destroying It. By L. O. Howard, Ph.D. Price $1.60 net. New York: Frederick A. Stokes Co., 1911.

To the author of this timely book is largely due our knowledge regarding the dangerous character of this common insect, and as long ago as 1900 he called attention to the transmission of typhoid fever by means of it. In this book Dr. Howard gives a clear and interesting description of the house fly (to which he gave some years ago the name "typhoid fly"), its habits, breeding places, etc., its natural enemies, and the means for its extermination. A valuable chapter is that on the carriage of disease by flies in which the charge against this enemy of man is proved beyond any gainsaying. The author insists upon the necessity of concerted action in the war upon the insect and offers suggestions as to organization, publicity, etc. The book concludes with a chapter on flies other than *Musca domestica* which frequent houses, some of which may possibly in certain cases also be disease carriers, but which do not deserve the name of "typhoid fly."

The Reduction of Domestic Mosquitos.—Instructions for the Use of Municipalities, Town Councils, Health Officers, Sanitary Inspectors, and Residents in Warm Climates. By Edward Halford Ross, M.R.C.S. Eng., L.R.C.P. Lond.; Liverpool School of Tropical Medicine; Late Health Officer, Port Said Canal District; Author of "The Prevention of Fever in the Suez Canal." With Illustrations. Price $1.75. Philadelphia: P. Blakiston's Son & Co., 1911.

This is an excellent, brief, but very practical treatise on the best methods for the extermination of the mosquito in town and villages. The book is founded upon an experience gained by the author in his campaign against mosquitos along the Suez Canal. The varieties most commonly found there are *Culex fatigans* and *Stegomyia calopus*, but the measures found useful in reducing the number of these will be equally efficacious in the warfare against those of the genus *Anopheles*. The book is most timely and those public spirited citizens who are now conducting campaigns against this pestiferous and exasperating insect will find many hints of value in these pages. The book is eminently practical, being founded upon actual experience.

Compend of Gynecology. By William Hughes Wells, M.D., Associate in Obstetrics in the Jefferson Medical College; Assistant Obstetrician in the Jefferson Medical College Hospital; Fellow of the College of Physicians of Philadelphia, etc. Fourth edition, revised and enlarged; with 153 illustrations. Price, $1.00. Philadelphia: P. Blakiston's Son & Co., 1911.

In this revision the author has eliminated descriptions of operations and other methods which are now out of date. The book contains all that a student is likely to look for; and it will prove useful to those who have to make a hurried review for some State Board (or other) examination. The numerous tables of differential diagnosis constitute one of the features of the work, and the illustrations are well selected. In a future edition the subject of gonorrhea might well be treated a little more in detail.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Articles on Treatment, Medicine, Surgery, etc. By Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, U. S. A. Volume I, Twenty-first Series, 1911. Price, $2.00. Philadelphia and London: J. B. Lippincott Company, 1911.

The opening volume of the new series of this well known quarterly contains numerous articles of interest to the specialist, as well as to the general medical practitioner. Thus Zeller writes a paper on the spread of pellagra in the United States which shows how extensive this disease has become in the last few years, over 7,000 cases being accounted for. Wechselmann gives further personal experiences with salvarsan; his views are very favorable to the new specific. Faught describes the many sphygmomanometers now on the market, including two forms of his own apparatus; Jump follows with a paper on the value of blood pressure estimation in internal medicine. Mills has an extensive article on the clinical investigations of poliomyelitis, material being gathered from a study of 45 cases of the disease. Thomas writes on open treatment of fractures and the use of plates and screws in holding fragments. Carl Beck prints a clinical presentation of several interesting surgical conditions. Hall summarizes the recent advances in our knowledge of nutrition. These few selections from the contents show the widely distributed subjects treated in this volume. In addition to original articles progress of medical art and science in treatment, medicine, surgery, etc., is shown by complete abstracts of the more important papers recently published. A collection of the successive volumes of this periodical forms a very valuable addition to a practical man's medical library.

Differential Diagnosis. Presented through an analysis of 383 cases. By Richard C. Cabot, M.D., Assistant Professor of Clinical Medicine, Harvard University Medical School, Boston. Profusely illustrated. Price, $5.50. Philadelphia and London: W. B. Saunders Company, 1911.

If one had the power in some astral manner of accompanying a distinguished clinician upon his hospital rounds and upon his consultation appointments, and furthermore, of discerning every step in the latter's mental processes by means of which a diagnosis is arrived at, no greater advantage would be gained than by a perusal of a book such as this. As we turn its pages our wonder grows that until Dr. Cabot had conceived the happy idea underlying the execution of this work, no one had ever made the attempt of writing a book exactly along these lines. Its keynote is the study of medicine from the viewpoint of the presenting symptom; that is, the symptom chiefly for which the patient comes to the physician for relief. The author recognizes the presenting symptom as a fragmentary expression of the underlying disease, which symptom is to be followed as a lead to the actual seat of disease. The symptoms most frequently complained of by patients are taken up separately, their common causes presented and classified in the order of their frequency, with the aid of "gridiron" diagrams, and furthermore illustrated by case histories in which the presenting symptom is followed home until a diagnostic problem and its solution are presented. Thus, the opening chapter of the book deals with the subject of pain, its general considerations, degree, types, relation to other facts, habit pains, and the theories regarding the production of pain. The following chapter takes up the subject of headache, discussing its numerous causes, and illustrating these by means of a "gridiron" diagram constructed from an analysis of numerous statistical investigations. Then follow twenty-two case histories, in which headache was a prominent symptom, and in which the operations of the diagnostician's mind are fully revealed as, step by step, with careful consideration of all the possible causes, and with a judicial balancing of all the available evidence, a diagnosis is finally reached. This is the plan followed throughout the book in the discussion of lumbar pain, epigastric pain, pain in the arms, etc., fevers, chills, coma, convulsions, cough, vomiting, hematuria, dyspnea, jaundice, and nervousness. In the selection of cases the author has chosen none in which the diagnosis was obvious and none in which it was impossible or depended chiefly on good luck. The cases are not the cut-and-dried models patterned after the usual textbook descriptions, but are actual cases such as are found in everyday hospital and private practice. It requires years of experience for one to appreciate fully the process of reasoning by means of which in each instance the diagnosis is deduced from the available evidence, and it is with a sense of pleasure no less than of profit that one turns the pages of this book. The discussions appended to each case provide not only a mirror of the reasoning process of the trained clinician, but furnish also many wise conclusions derived from a rich experience. "Unresolved pneumonia is mostly a myth; in the vast majority of cases it spells empyema." This is an example of the many pithy utterances with which the book is studded. In the conciseness and elegance of diction with which the case histories are presented the style of the author may serve as a model. Some errors have crept in; future editions will no doubt correct the frequent reference to the Kernig symptom as the "Koenig" symptom, and the use of the word "sputa" for sputum.

Food and Feeding in Health and Disease. A Manual of Practical Dietetics. By Chalmers Watson, M.D., F.R.C.P.E., Assistant Physician, Royal Infirmary, Edinburgh; Editor of the "Encyclopedia Medica." Price $4.00. New York: William Wood & Company, 1911.

In reading the pages of this book one is impressed with the fact that the author has fully accomplished his aim in presenting a work that is practical. No treatise on dietetics can be regarded as satisfactory unless it is eminently practical. In the multiplicity of details associated with his daily work, the practitioner requires definite information on various subjects, in a form that is not buried amid a mass of theoretical discussion. This is also true of the medical student, who, with his overcrowded curriculum, demands that the textbook should furnish the essentials of each subject in a form that is complete and satisfying. This book apparently satisfies the needs of both student and practitioner. It presents the broad foundations of dietetics, the physiology of digestion, the nature of foods, the normal laws of feeding, and the deviations affecting these laws, as an essential preliminary to the more practical aspects of the subject. The author has followed the general trend of recent advances in the physiology and pathology of digestion, by placing greater emphasis than usual upon the influence of food on the digestive and bacterial processes in the gastrointestinal tract. The various animal and vegetable foods and proprietary preparations are fully described, together with the culinary art by means of which these may be combined in menus agreeable to the invalid. There are chapters on food preservatives, food adulteration, and diseases caused by food; diet at different periods of life; underfeeding and overfeeding; general serving of food for invalids and rectal feeding; infant feeding; and chapters on the dietary of various clinical entities and groups of diseases. Of special interest are the chapters devoted to the dietetic management of diseases of the stomach and intestine, arteriosclerosis, diseases of the kidney, tuberculosis, gout and allied conditions, glycosuria and diabetes, and obesity. There is a separate chapter on special diet cures, such as vegetarianism, purin-free diet, Salisbury diet, etc., and one on hospital dietaries. One admirable feature of this book is the inclusion under each disease of various detailed menus to which the practitioner may refer for guidance. This reference is furthered by a particularly complete index. There is an appendix comprising a series of papers which have been published within recent years by the author and by others, all of which deal with experimental investigations on the influence of diet on the structure of the tissues. This section of the work should prove particularly helpful to those who are interested in the experimental aspects of dietetics. The experience of the author as editor of the "Encyclopedia Medica" is discerned on every page in the literary skill with which the prosaic matter of this work is handled. In elegance of typography, paper, and binding there is nothing left to be desired. One may recommend this book without reserve as a valuable addition to the literature of dietetics.

Principles of Public Health. A Simple Text Book on Hygiene, Presenting the Principles Fundamental to the Conservation of Individual and Community Health. By Thos. D. Tuttle, B.S., M.D., Secretary and Executive Officer of the State Board of Health of Montana. Cloth, 60 cents. Yonkers-on-Hudson, New York: World Book Company, 1910.

In this compact little volume of 186 pages are treated many topics relating to health and its preservation. The chapters are arranged under two headings: "The Fight for Health" and "The Enemies of Health." Among the subjects considered in the first part are clothing; the uses, care, and decomposition of food; neatness, cheerfulness, and good manners; the necessity for pure air and rest; and the care of the skin, eye, and ear. In the second section are chapters on disease germs and their transmission by insects, air, and water. As this book is intended for use in the public schools only such preventable diseases are discussed as the author deems wise to present to school children. The style is interesting and concise, and a series of questions and summaries at the chapter ends are of value in the school routine.

Mikroskopiske Undersögelser over Bugspytkirtelens normale og patologiske Anatomi. Hvorunder Forholdene ved en del Tilfaelde af Sukkersyge. Af K. A. Heiberg, Klinisk Assistent ved det Kgl. Frederiks Hospitals Mediciniske Afd. A. Köbenhavn, Andr. Fred. Höst & Son, 1910.

Unfortunately this monograph is written in Danish and consequently can be of but limited value to the profession in this country. The line of investigation is one already outlined by Opie and others; that is, the determination of the number of the islands of Langerhans in the pancreas in normal persons and in persons suffering from diabetes. The photomicrographic illustrations and the drawings are admirable in execution and in reproduction.

Stoffwechsel und Stoffwechselkrankheiten. Einführung in das Stadium der Physiologie und Pathologie des Stoffwechsels für Aerzte und Studierende. Von Prof. Dr. Paul Friedrich Richter, Privatdozent an der Universität Berlin. Zweite Auflage. Price, 8 marks. Berlin, A. Hirschwald: 1911.

The first edition of this useful volume on metabolism was issued six years ago. At that time it was one of the best books on the subject. Since then, however, the growth of our knowledge of the chemical processes of the body has been rather remarkable, and unfortunately many points have been omitted by the author in his revision. The technical methods for analyses have not been brought up to date, many of those given in the text having now been replaced by simpler procedures. The volume still remains, however, a useful summary of the chief facts known in regard to metabolism, both in health and in disease.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Forty-First Annual Meeting, Held at Spring Lake, June 13 to 15, 1911.

Oration in Surgery: The Education of a Surgeon.—Dr. Joseph A. Blake, of New York City, delivered this oration. He said that in our school and hospital organizations no provision was made for the systematic training of surgeons. The education of a young surgeon was carried out systematically and well until he reached the end of his interne service in a hospital. Then he was left to his own resources until he got a hospital appointment as visiting surgeon. The period between these two appointments averaged at least five years, years that were the most impressionable and therefore the most valuable in a receptive sense. Even when he became a visiting surgeon, his services were short and spasmodic; and until he acquired a large private practice his experience was in no way continuous. To remedy this state of affairs Dr. Blake proposed that in the large hospitals having continuous services a post-graduate course of six years should be created. For this course men should be selected from the outgoing surgical house staff of the hospital. They should each serve one year as assistant resident, one year as resident, two years as assistant visiting surgeon, with assignment of duties in the laboratories of surgical pathology and experimental surgery, in addition to duty in the wards and operating room; and two years as assistant visiting surgeon, with duties in the out-patient department, as well as the wards and operating room. In these last two years the appointees should also be demonstrators of anatomy in a medical school. Such a course could be carried out to advantage only in a university hospital. The full organization of a surgical staff for such a hospital of one hundred beds should be a chief, or director of the surgical staff; a visiting surgeon; two associate visiting surgeons, all of which should be permanent positions, and four assistant visiting surgeons and two resident surgeons, constituting the rotating members of the staff, as above described. It was believed by the reader of the paper that such an arrangement would be of great benefit to the young surgeons, who would get a splendid experience, including pathology and anatomy, and should be able to fill with credit any hospital position to whch they mght be called.

Splenectomy.—Dr. John C. McCoy of Paterson said that splenectomy was indicated in certain conditions causing an enlargement of the spleen, interfering with the health of the individual ,and for the reason that an enlarged spleen was a source of danger to the patient, owing to its susceptibility to laceration in trauma, or even to rupture without external violence. The spleen probably took an active part in disposing of broken-down blood cells; but in no reported case had its removal been followed by conditions that could be attributed to its absence. In both his cases of extirpation following traumatism of the spleen, eighteen months and seven months after operation, respectively, the general condition seemed to have remained as good as it was prior to the loss of the organ. Both had gained in weight and were able to take part in athletic exercises. Certain changes in the blood seemed to be constant following splenectomy; but it was only a question of time when the blood constituents should again reach a normal state. During the past three years Dr. McCoy had seen four cases of rupture of the spleen, two of which could be attributed to direct violence. Removal of the spleen was followed by a fatal result in one of these cases. The diagnosis of contusion of the spleen causing an enlargement of that organ from intercapsular hemorrhage could, he said, be made only upon the previous history of trauma; nor was it possible to differentiate this from a tumor of the spleen due to other pathological changes that might have been present prior to the injury. A patient showing splenic symptoms following trauma in this region, particularly if accompanied by abdominal rigidity, should be carefully observed for subsequent rupture of the spleen. The diagnosis of rupture of the spleen was difficult, the clinical picture not differing materially from intraabdominal hemorrhage due to rupture of other organs. The pressure resulting from the accumulation of blood from a ruptured spleen might cause urinary symptoms closely resembling those found in rupture of the kidney. Sometimes a careful rectal examination would reveal an elevation of the posterior parietal peritoneum of the left side, due to the hematoma from the ruptured kidney, this symptom being absent in splenic hemorrhage.

Dr. Robert M. Curtis of Paterson said that the most interesting feature brought to his mind by these cases was the well-worn diagnosis of internal injury. Physicians should not be content to make this diagnosis and then let the patient die. An early diagnosis of the true condition should he made, but medical men were excusable if they did not depend upon that refinement of diagnosis which led to a positive determination as to which particular organ was or was not ruptured. The surgeon should be allowed to open the abdomen and make the exact diagnosis afterward. The proper time to do this was at once, not waiting until the patient was ready to die. The same kind of blow might cause either rupture of the spleen or rupture of the kidney, or both. Many cases of the latter would recover spontaneously, while it is better to operate in all cases of rupture of the spleen. One should, however, be conservative about operating on patients for a diseased condition of the spleen, as the mortality from such operations was very high.

Dr. McCoy said that in both his cases the operation was deferred because, though there was hypertrophy of the spleen, it was questionable whether this had not been present before the accident.

Chronic Gastritis of Secondary Origin, Presenting the Phenomenon of Achlorhydria Hemorrhagica Gastrica.—Dr. James T. Pilcher of Brooklyn, who read this paper, stated that chronic gastritis was frequently traceable to reflexes emanating from irritation in distant organs. The primary etiological conditions should be appreciated and receive treatment, rather than the result in the stomach itself. The object of the paper was to indicate the deductions to be drawn from the single symptom, viz., absence of free hydrochloric acid and presence of occult blood. Observations were made from examinations in a series of 4,000 patients. Of this number 271 presented the symptoms in question. Of these 271 patients, in 156 the onset of the gastric symptoms was traceable to certain infectious diseases, circulatory disturbances, derangement of ductless glands, and various forms of abdominal operations; in 100 others the symptoms of extragastric pathological conditions were evident and exploratory operations were done, revealing distinct involvement of the appendix in 36, involvement of the gall-bladder in 32, involvement of the gall-bladder and pancreas together in 16, and involvement of the gall-bladder and appendix together in 12. The reflex stimulations received by the stomach from distant organs, the author said, might be evidenced in several ways; as, for example, by hypersecretion or pylorospasm. Of the 100 cases of achlorhydria hemorrhagica gastrica operated upon, in 24 there was a distinct spasm of the pylorus, accompanying appendicitis 18 times, and gall-gladder involvement 6 times. In conclusion Dr. Pilcher said that intermission of hydrochloric acid was a reflex nervous phenomenon; and that the view that the gastric lesion was not the causative factor was

supported by the fact that in 88 of the 100 abdominal explorations in which there were direct exploration and palpation of the stomach no gross change in the stomach walls could be demonstrated. Bacterial flora were a second factor in the production of this symptom, *i.e.* achlorhydria hemorrhagica. Large numbers of bacteria were always present in the fluids extracted from the stomachs in these cases. Streptococci, diplococci, and colon bacilli were almost always found. The growth of these bacteria was dependent solely upon the lack of the inhibiting action of the hydrochloric acid. A third factor was the presence of superficial erosions of the mucosa and round-cell infiltration. The diagnosis was to be determined by the analysis of the stomach contents. Free hydrochloric acid was never present, and the blood reaction was always present.

Dr. Thomas W. Harvey of Orange said that there was no organ that might not send a reflex influence back to the stomach, causing to appear in that organ symptoms often so severe as to cause one to overlook the original disease. Physicians were often misled by a long name, forgetting that these titles were only names of symptoms, or possibly neuroses or aberrations of function, and conveyed no pathological meaning. He thought that usually too little attention was given, in studying the etiology, to the effect of continuous disturbance of function as a cause of pathological changes. Changes in the nervous or circulatory supply of a distant organ would have an important reflex influence upon the stomach and its secretions, and this, operating continuously, might easily induce a train of symptoms simulating or even producing serious pathological conditions.

Dr. Frank D. Gray of Jersey City remarked that the necessity, in every symptom presented, however trivial, of making a diagnosis by exclusion was too frequently forgotten, because a snap diagnosis was so very easy, and to unravel all the etiological factors in the case required considerable time. No one should pass over a case without knowing what a test for free hydrochloric acid and a test for occult blood would show. These tests were not beyond the capacity of the general practitioners, but if they did not feel competent or had not time to make these tests themselves most of them were within reach of a pathological laboratory. Dr. Gray then asked Dr. Pilcher whether the pathology of the stomach was due to nervous influence or to the presence of bacteria, creating mild inflammatory changes in the mucosa.

Dr. Pilcher replied that of the eight or nine thousand patients complaining of nothing else than stomach distress that he had lately had the good fortune to examine there were not more than 10 or 15 per cent. who had any organic change in the stomach itself. Their trouble was in most instances a reflex one. He had chosen this Latin name chiefly because it would be too long to express conveniently in English. He wished, however, to impress upon them the fact that it was the name of a symptom, and not a disease. Patients complaining of stomach distress should not be treated for the thing of which they complain, except incidentally. The symptomatology should be inquired into and a careful history taken. From the symptomatology of ten to twenty-five years before one might get an inkling as to what the primary etiological cause was. He considered the importance of the analysis of the stomach contents greatly overrated, and stated that only one absolute diagnosis could be made from it, that of stenosis. It seemed to him reasonable to suppose that this condition of the gastric mucosa was produced by the action of bacteria subsequent to the diminution in the amount of hydrochloric acid.

Final Results in Surgery.—Dr. Otto Kiliani of New York City presented this paper. He said that, since the ability of the surgeon was gauged by his immediate operative results and the short length of time that the individual patient occupied a bed, most patients were dismissed from the hospital as healed, but not cured; and the interest of the surgeon in his cases and his knowledge of them ceased with the dismissal of the patients from the hospital. Any one attempting to collect statistics of the actual end surgical results was confronted with the impossibility of following up the cases. The difficulty in estimating the relative value of different methods of operating in certain diseases was that very frequently ten or fifteen years must elapse before the final results could be determined. In only a few instances were the final results known to the surgeon; it was the family physician who was aware of them. The patient, however, was the only proper person to judge of the final results of the operation performed on him. The wound that healed by primary union, Dr. Kiliani said, gave the best results. As soon as infection took place the final results were at once endangered. The study of final results in amputations and fractures was much facilitated by the use of the *x*-ray. Among surgical accidents the unintentional severing of the facial nerve during mastoid operations or in the extirpation of glands in the neck was so terrible that, to his mind, the patient would have been better off without an operation, even though his condition had led to death. The general practitioner, who was so much better able to judge of the final results than was the surgeon, should publish these or enable the surgeon to do so in that ever desirable collaboration of internal medicine and surgery which was so necessary for each of them.

President's Address: A Plea for Attaining and Maintaining a High Standard of Medical Education.—Dr. Thomas H. Mackenzie of Trenton said that it was the duty of the State to protect the public from unscrupulous practitioners by enacting laws that would eliminate entirely from the practice of medicine those not qualified for such service. Qualification was determined by measurement with some standard. A medical education standard should be established. The Federal Government should enact a law creating a Bureau of Medical Education and Sanitation, one of whose duties should be to establish a standard for preliminary medical education. A degree from a medical school would then be a guarantee of efficiency. The over-production of ill-trained men was mainly due to the existence of commercial medical schools. Medical science could make but little progress while it depended upon such mercenary institutions as its source of inspiration. A Federal Bureau would have the power to regulate this evil. In the absence of such a bureau we must look to the progressive, public-spirited, and well-endowed medical schools, to the State Medical Boards, and to whatever results might be obtained from the agitation instigated by the American Medical Association. Improvement in medical education had been rapidly accomplished since the organization of the Council on Medical Education in 1904. The Association of American Medical Colleges had discussed the standards of medical education with a view to their improvement. The result was that nearly all colleges were requiring, in addition to the high-school course, one or more years of college work. The good offices of the New Jersey State Board had been somewhat handicapped by the defective laws regulating medical practice. The Medical Society had for three successive years asked in vain for relief. The Legislature seemed to suspect that the doctors had asked for legislation for their own selfish ends. The mind of the general public should be disabused of such false notions. The medical profession should organize a campaign of education and seek to set the matter in the proper light.

Advances in the Knowledge of the Circulatory System.—This was the oration in medicine, and was delivered by Dr. George W. Norris of Philadelphia, who,

after briefly outlining the gradual development of our knowledge of the circulation from the earliest historical times, proceeded to a discussion of the relatively recent methods of study. He said that percussion, auscultation, etc., would probably never be suspected; but that they had been materially abetted by various procedures. Among these the auscultating method of estimating blood-pressure, especially by a study of the five phases of Korotkow, the practice of sphygmography, the orthodiagraph, the electrocardiogram, and the plethysmograph were respectively discussed. The relative merits of various instruments were pointed out. The primary importance of dirt, hygiene, mode of life, and of physical methods of treatment was urged in contradistinction to the secondary rôle of drug therapy. The practice of massage on the part of the youthful and less busy practitioner would save many a patient from the osteopath and his kin. Thanks to recent investigations, much more accurate knowledge regarding digitalis and strophanthus was available and much more reliable preparations were to be had. The newer patented preparations of the former drug had not proved sufficiently superior to the ordinary preparations to counterbalance the increased cost. The newer conceptions regarding the cardiovascular system in health and disease were alluded to, viz., the myogenic doctrine; the importance of vascular, as well as cardiac, compensation; the frequency of syphilis as an etiological factor; and that of low-grade chronic infection as a cause of progressive endocarditis.

The Advantages of the Autopsy and Other Pathologoanatomical Examinations.—Dr. Harrison S. Martland of Newark said that, on account of lack of time, he would speak only of the advantages of the autopsy, omitting a discussion of frozen section work and other pathological and anatomical eaminations. He stated that the greatest importance of the autopsy was shown in the proper signing of the death certificate. Clinicians who had followed their cases to the autopsy table would admit that a large percentage of them were ones of mistaken diagnoses. The filing of vital statistics by the Census Bureau, for instance, on the causes of death in the United States was a very amusing procedure, since in only a small percentage of the cases was a control by autopsy made. Jacobs, in the campaign against tuberculosis in the rural districts of Germany, had advised that an obligatory examination of all dead bodies should be required for one or two years for the purpose of a more exact determination of the mortality from tuberculosis; and Dr. Martland considered the clinical diagnoses in this country far too faulty to be accepted for statistical purposes. Vital statistics concerning death would, he thought, be greatly improved if all the States would adopt an appendix to the death certificate for the purpose of filing the pathological anatomical cause of death when an autopsy was performed. The greatest scientific advantage of an autopsy was seen in the combining of the anatomic lesions at autopsy with the clinical picture of the disease. In order to obtain this a constant commingling of the clinicians and pathologists in the wards and laboratory was necessary. The combining of clinical data to formulate a diagnosis, and the proof of the correctness of the clinical data, constituted the only ideal method of teaching medicine. Clinicopathological courses should be required in all medical schools as the basis of the medical teaching. Pathology and medicine should be taught side by side, in the hospital and the morgue; and not by separate didactic lectures. Dr. Martland believed that another advantage of the autopsy would be in the restraining of the modern idea of specialization. Autopsies frequently exposed the narrow-mindedness of various specialists, even the most talented of them. He illustrated, in more or less detail, the importance of the autopsy, as shown by a few cases selected from 500 consecutive autopsies performed at the Newark City Hospital from 1909 until the present time. He did not include among these cases of primary kidney, heart, liver, or cardiovascular disease. He then stated that the advances made in experimental biology and pathology had proved that most monstrosities originated in the earliest periods of the segmenting ovum. Hence the rôle played by superstition in the past should no longer exist. It was surprising how, in the case of diaphragmatic hernia, life existed for many years with gross deficiency of the parts. He called attention to the presence of patent foramen ovale in numerous adult autopsies; but said that it must be remembered that during life the opening might have been practically closed by the blood stream.

Dr. John C. McCoy of Paterson said that there were two phases of this work that seemed to him both encouraging and profitable. One was to be able to study the end results of repair and the effects of various ways of applying sutures, so as to be able to determine what to do in similar conditions in other cases. The other was the study of severe injuries of the head, either from traumatism or gunshot wounds, so as to be able to make the differential diagnosis between operable and inoperable cases. Fractures of the skull should be looked upon just as other fractures were. To get good results one should overextend the force that has caused the fracture, thus dislodging the bone at the point of fracture and being able to get it back into place.

Dr. Walter B. Johnson of Paterson said that the pathologist had the advantage of a condition in which he was permitted to determine absolutely the state existing; whereas the physician or surgeon must take into consideration the conditions that might be existing. It was only by a study of these conditions at autopsy and their investigation in the pathological laboratory that the possibility of being more certain in one's judgment concerning the conditions existing during life could be attained prior to the time when the decision to perform an operation might assist in saving the life of the patient.

Dr. Frank W. Pinneo of Newark said that observation could not be perfected unless one had followed the case to autopsy and seen what could not be discovered from the outside. Autopsies might be obtained in private practice more frequently than they were, and were often not performed in private cases when they would have been had the patient died in the hospital.

Dr. Edward W. Worl of Newark remarked that in compiling vital statistics one sometimes came across diagnoses that could not be classified by any system. Official autopsies would settle the question in many cases of this kind. It seemed to him, however, that in some cases of infectious disease the anatomical findings would not correspond with the essential etiological factor. There should be a law in the State to compel an official autopsy in every case, no matter what the diagnosis of the family physician might be.

A Needle Carrying a Single Strand of Suture Material.—Dr. H. D. Corbusier of Plainfield stated that the advantage of this needle was that there was not the double tearing of the tissues when it was used that occurred when a double strand of suture material was pulled through; also, the surgeon could work faster, tie more quickly, and use less suture material. The needle had an eye in the base and a jaw that caught the catgut. The thread was passed into the needle and cut off, no suture material being left protruding. When the single strand was used the hole made by the needle was not enlarged.

Some Diseases of the Gall-Bladder.—Dr. Frank W. Donohue of New Brunswick read this paper. He stated that the diseases of which he wanted to speak particularly were cholecystitis, cholelithiasis, and cancer of the gall-bladder. In looking over the etiology of gall-bladder diseases it was found that in almost every case they were

caused by infection, not only infection of the gall-bladder itself, owing to the presence of gallstones, but also infection from the other organs of the abdomen. If pressure was made over the region of the common duct (steady, continuous pressure) and the patient with suspected gall-bladder disease told to breathe long and deeply, one would find that, as the pressure was increased, he was unable to take a long, deep breath. In order to make a diagnosis of floating kidney the patient should be made to stand up or lean forward a little rather than to assume the recumbent position. The pain of gall-bladder disease was always referred to the right hypochondriac region, shooting to the shoulder-blade and radiating up to the right shoulder. Jaundice occurred in about 30 per cent. of the cases of gall-bladder disease. It was caused by interference in the common duct with the passage of bile from the gall-bladder and liver to the duodenum. This interference might be produced by a stone or by the swelling brought about by the irritation due to the passage of a stone. Dr. Donohue had never been able to demonstrate the existence of stones in the gall-bladder by means of the *x*-ray. The prognosis in gall-bladder disease was almost invariably good after surgical treatment, except in the case of cancer. He had long ago ceased to treat well-marked gall-bladder diseases with drugs. The incision that he preferred was a straight one through the right rectus muscle. Drainage of the gall-bladder he looked upon as essential to the recovery of the patient.

Dr. Edward J. Ill of Newark wished to call particular attention to the so-called sensitive points in the abdomen as being exceedingly misleading. For instance, in the more important cases McBurney's point was entirely lost. It was the same with the other points. In looking for Morris's point one might get into difficulty in cases of movable kidney.

Dr. Gray, as to the differential diagnosis from movable kidney, took issue with the reader of the paper concerning the greater facility in diagnosing movable kidney with the patient standing than in the recumbent position. He found that patients, on standing or stooping slightly, became rigid. When they were lying on the back with their knees flexed he had usually found it easy, on deep inspiration, to make out a movable kidney. In gall-bladder cases there was often so-called hunger pain and the gall-bladder attacks were most likely to occur nocturnally, more frequently in the latter part of the night.

Dr. B. Van D. Hedges of Plainfield said that one thing that had deceived him in the differential diagnosis was a central pneumonia involving the right lower lobe in children. He had recently had a case of this kind, with diaphragmatic pleurisy, whose symptoms exactly resembled those of gall-bladder disease. There was no indication of any involvement of the lung until after four days. In young children gall-bladder disease was very rare, the speaker said; and one should be chary of making a diagnosis of that until one has waited long enough to exclude pneumonia with diaphragmatic pleurisy.

Dr. Donohue admitted that if one made direct and firm pressure over the kidney while the patient was standing up the muscles of the abdomen would contract and become rigid, and it would be difficult to make out floating kidney; but said that if one made firm, gentle pressure and gradually increased it and then, when the lump was found, made a slight pressure over that and gradually increased it, one could almost always make out floating kidney.

Excision of the Superior Maxilla for Sarcoma of the Antrum.—Dr. Walter B. Johnson of Paterson stated that the patient was a woman thirty-three years of age, with no history of cancerous disease. The injury, which occurred one year previous to operation, was followed by swelling, which persistently increased. It involved and filled the nostril, exfoliated the teeth, perforated the palate, entered the orbital cavity, and involved the nasal and ethmoid bones. The operation was performed in the usual manner, curetting the ethmoid. The patient was discharged in three weeks. The pathological report was alveolar sarcoma cells, spindle-form variety, arranged in distinct nests. The patient, at the time of the report, could do any kind of work that she ever was able to do. At this time, fourteen months after the operation, no symptoms of recurrence of the disease were evident.

Report of a Case of Foreign Body in the Eyeball, in Which the Excessive Pain Was Relieved Immediately After Radiography.—Dr. Walter B. Johnson stated that the foreign body was in the eye for one week. Then pain began, increasing daily, with diminution of vision. At the end of the second week, after the use of radiography for the purpose of locating the foreign body, the pain left and the inflammation subsided. Vision returned and the foreign body became encysted in the sclera. Did radiography cause this change? he asked.

Dr. John G. Ryerson of Boonton said that in a case in which he had removed the upper jaw, thirty years ago, for fibrous tumor, he had made the incision in the usual way down the median line of the mouth and palate. Then, by drawing the teeth aside, he was able to cut with a sharp instrument over the junction of the palate bone with the other bone and enucleate and remove the tumor, leaving the palate bone behind. Afterwards, the cavity was filled by a dentist, leaving almost no deformity. The danger in this operation was that of getting blood in the trachea. To avoid this the head should be allowed to hang over the edge of the table.

Dr. David T. Huston of Philadelphia said that Dr. Johnson had referred to the difficulty in controlling hemorrhage. Recently Dr. Huston had had to remove the maxilla, and in doing this he felt that the vessels in the posterior and accessory palatine canals had to be reckoned with. In order to control this hemorrhage he conceived it to be best to ligate the external carotid artery. This rendered the removal of the maxilla almost bloodless. The artery should be ligated in the neighborhood of the greater cornu of the hyoid bone, and there would be no danger of any infection of the ligation wound through the removal of the maxilla above; though this was not the case in the removal of the mandible. By calling into requisition the services of a good dentist it was possible to replace the maxilla by an artificial bone and thus preserve the speech of the individual.

Dr. William J. Lamson of Summit said that in many cases it was possible to remove the upper jaw with just a single lip incision. In this way disfigurement might be avoided to a great degree.

Dr. Elbert S. Sherman of Newark said that it seemed like an unusually good result in Dr. Johnson's first case, because there is almost always a rapid return of these growths. He had a similar case at present, which he had been advised to let alone. He had had given to the patient an injection of sulphur sand, in the hope of producing some improvement, great improvement having been reported in a similar case. Whether he was making a mistake in letting this alone he did not know.

Dr. William S. Schauffler of Lakewood had found that the interrupted *x*-ray gave the good results of the ray without its bad effects. Dr. Schauffler considered it absolutely safe, and said that he had had a large number of cases with no disagreeable results.

Dr. George H. Balleray of Paterson thought that preliminary tracheotomy obviated to a great degree the danger of hemorrhage into the trachea.

Dr. Carl E. Sutphen of Newark said that treatment of the eye with the *x*-ray was novel to him, though he knew that it has been employed. Dr. Johnson's case was one in which one might expect panophthalmitis. The only way

in which the *x*-ray might relieve such a case, so far as he could see, was by the destruction of germs. His impression, however, was that this result was merely a coincidence. The pain was due to the inflammatory condition caused by the foreign body, and one often heard of great and increasing pain suddenly getting better. Probably when the foreign body became encysted and worked its way out to the external portion of the eye the pain became relieved.

Dr. Johnson had not meant to say that there would be no recurrence of the malignant growth in this case; but up to then there had been none. The vision had remained normal, regardless of the fact that the orbital plate of the malar bone had been destroyed. If this woman needed a dental plate he would have to buy it for her, as she was very poor. The reason that the hemorrhage was alarming in this case was that, on account of the friability of the bone, he had to work slowly and could not get at the vessels that were bleeding so quickly as would otherwise have been the case. He thought that by the use of care one could usually keep the throat pretty clear of blood, so that tracheotomy would not be necessary. In regard to the *x*-ray he said that the reports of the results of this treatment were not very satisfactory. The question was not whether one should use the interrupted *x*-ray or not, but what could be done to effect a change in the metabolistic processes about the eye at the time of the application of an *x*-ray current.

The Early Diagnosis of Tuberculosis; Original Method.—Dr. Irving E. Charlesworth of Bridgeton stated that if tuberculosis had not been so difficult to detect early it would have been conquered generations ago and added to our long list of curable diseases. The onset was slow and insidious. The patient thought that he was run down and consulted a physician. If the latter could recognize the early symptoms the prognosis was quite hopeful; but if he made only a desultory examination and failed to discover the true condition the patient soon joined the large army of advanced cases and the prognosis became relatively grave. The decrease in the death rate from this disease was due not so much to the improved treatment as to the increased ability on the part of physicians to diagnose the disease in its early stage. The following symptoms should lead one to suspect the presence of tuberculosis and suggest a physical examination: Progressive loss in weight; an increase in the pulse rate, especially in the afternoon; slight fever, particularly if present between the hours of four and five in the afternoon; loss of appetite without apparent reason; unusual fatigue without a known cause; an attack or a history of spontaneous pleurisy; pain in the chest, especially in the interscapular region; a cough that persisted, especially following an attack of influenza, bronchitis, or pneumonia; a protracted convalescence following an infectious disease, especially after an attack of pneumonia, typhoid fever, or malaria; a slight cough, worse in the morning, at night, or on awaking from sleep; a history of blood-streaked sputum or pulmonary hemorrhage (about 20 per cent. of all cases had this for the first subjective symptom); a chronic indigestion, which persisted in spite of treatment. The best times for making examinations were in the morning for the pulmonary signs, and in the afternoon for the general symptoms. The examination should consist in inspection, palpation, percussion, and auscultation, with the patient stripped to the waist. Tuberculin should not be used until all other means of making the diagnosis have been exhausted. If it was necessary to employ it, this should be done by a careful and experienced physician, skilled in this particular branch of diagnosis. The *x*-ray was a valuable adjunct to our armamentarium, to confirm the findings of the physical examination. Sputum examinations should be made repeatedly. The presence of the bacilli usually indicated an advanced stage of the disease, but it might mean the softening and emptying of a node directly into the bronchial tube; the latter would be in the early stage. The presence of the bacilli was not necessary for the diagnosis; since only in half of all the cases were they found, and only in 2 per cent. of the incipient cases.

Dr. Samuel B. English of Glen Gardner said that the greater number of those that died in the first two years after being accepted for life insurance died of tuberculosis. The fact of their not having been discovered at the time of making the application must be due rather to carelessness on the part of the examiner than to ignorance. The greater portion of patients with advanced tuberculosis must have consulted a physician for some reason or other when the disease was incipient. Sometimes the physician knew the disease was present, but did not like to tell the patient so. It was exceedingly important that the diagnosis be made before the tubercle bacilli could be found in the sputum. It was almost a crime to make but one examination of the sputum and tell the patient that he had not the disease. Not enough attention was paid to the kind of stethoscope used in examining the patient, as a faulty one might prevent the hearing of sounds that would otherwise be heard. A patient who had ever had tuberculosis always had it, even though he was able to work for his living. Unless he took the greatest care the time would come when he would be as sick as he was at first.

Dr. Philip Marvel of Atlantic City said that greater stress should be laid upon the history. In the majority of the cases in which there was an absence of the bacilli the physical signs and the history were the only things upon which one might make a diagnosis. The fact that one did not find bacilli did not show that none were present, but merely that none were present in the sputum examined. It was probable that the bacilli were not actively thrown off in the sputum unless there was a concurrent infection.

Dr. B. S. Pollack of Jersey City thought that if the bacilli were found a great deal of tissue destruction had taken place, and the case was no longer in its incipiency; though there were some very rare cases in which small tubercles became dislodged and expectorated. In the institution with which he was affiliated, there were 490 cases of tuberculosis last year, only 8 of which were incipient. Therefore, he thought that this term should be dropped. Very few of the cases were incipient; they were merely able to work. While the remark regarding the stethoscope was *à propos*, he thought that nothing could take the place of good hearing.

Dr. Theodore F. Corwin of Newark said that in every case in which a patient had been under treatment for a long time for nervous exhaustion a very particular search should be made for tuberculous infection. Dr. Charlesworth had referred to a lack of resistance as not being the only factor controlling the invasion of tuberculosis. Dr. Corwin believed that we should all have tuberculosis if we did not have plenty of tissue resistance. The function of the physician was mainly to build up that resistance.

Dr. Alexander Armstrong of White Haven, Pa., said that if one examined one's patients as they came, according to the rules laid down by Dr. Charlesworth, one would not overlook any cases. The trouble was that physicians who saw these cases before the specialist saw them did not like to send them to a specialist. The sanatorium was simply an educational institution. The patients remained there an average of ninety days, and could not be cured in any sense of the word. A cure, if accomplished, would take from three to five years. To call a patient cured, he must have been absolutely free from symptoms for ten years. After that, if he got another attack, it would be a distinct disease. The cases discharged from sanatoria

were merely relative cures. He granted that there was some danger in injecting tuberculin under the skin, but said that there was absolutely no objection to the use of the von Pirquet method for diagnosis. Every physician should be acquainted with the von Pirquet reaction. If any case known to be tuberculous failed to react the patient was dying. The reason that one did not get more cures was that physicians often gave the patients the foolish idea that a few weeks spent at a sanatorium would effect a cure. One should impress upon them that it would be a long fight, and that it could not be shortened.

Dr Ralph H. Hunt of Orange said that the most important physical sign was the presence of a fine râle. It was very necessary to get the family history, as these cases often spread from one member of the family to another. When a patient was sick enough to come to the dispensary one should look over the family; and the probability was that there would be incipient cases among them. He had never seen harm come from using the von Pirquet reaction. In regard to the cowardice of the average practitioner in not telling patients that they had tuberculosis, Dr. Hunt said that he saw many patients with advanced tuberculosis who had never been told that they had the disease. He admitted that it was painful to tell them the truth, but said that the end results would justify it; for it was the only way to get them to do the things necessary to save their lives.

Dr Charlesworth, in closing, emphasized the fact that in any family in which tuberculosis was found the other members should be examined. In half of the families in which there was a case of tuberculosis a case was found in another member. He urged them not to be afraid to tell the patients that they had tuberculosis, because then they could be taken care of.

Our Profession: Its Changes in Forty Years.—Dr. Enoch Hollingshead of Pemberton, in delivering the Address of the Third Vice-President, said that the medical profession had changed from one of individual empiricism to a standard seen through the microscopic lens, the researches of the laboratory, and animal experimentation. These researches had placed the profession upon a scientific basis and inscribed upon its banner that prevention was better than cure. Forty years ago pathology and histology were almost untaught in our medical schools. To-day they opened up a vista for the profession. In no way had that profession produced results greater than by the enforcement of sanitary laws unknown and untaught forty years ago. By this means the plague spots of the earth had been cleansed. The connecting of two oceans as the result of the enforcement of sanitary laws of medical men was the greatest achievement of the age, and the highest compliment to the profession save one; the placing of a man educated in medical, and not in martial, halls at the head of the military forces of the nation.

Significance of Pain in the Diagnosis of Disease of the Lower Abdomen.—Dr. Thomas B. Lee of Camden said that freedom from pain in benign tumors of the abdomen, particularly ovarian cyst, meant freedom from at least parietal adhesions, the converse being equally true. Pain in uterine conditions was referred to the lower parts of the back, near the top of the cecum, and to the hypogastrium. This was owing to the fact that its nerve supply was the hypogastric plexus, which sent fibers directly to the fundus; while the cervix was supplied by branches from the pelvic and ovarian plexuses. The ovaries, with practically the same nerve supply, were associated with the tenth dorsal segment, the pain being referred from them to the lower portion of the back and to the groin; while the characteristic ovarian pain was described as at a point two inches internal to the anterior superior spine of the ilium. Tenderness of the ovaries was frequently a misnomer, as slight pressure upon the hypogastric automatically rigid muscles over the ovary—elicited pain before pressure could be brought to bear upon the organ itself. The Fallopian tubes were connected with a segment higher up in the spinal cord, and the attempt to utilize this fact in the diagnosis of ectopic pregnancy unruptured had been made; but it seemed doubtful whether this could become of real value in the differential diagnosis. A long appendix, adherent to the bladder, might cause painful and frequent micturition, which might be the only evidence of appendiceal trouble; and a retrocecal appendix might cause intense and persistent backache. Localized peritonitis might give rise to pain in the lower abdomen. In differentiating this from other conditions that caused muscular rigidity and tenderness the following facts should be borne in mind: The pain in peritonitis was not referred pain. Referred pain was eased by pressure, whereas the pain in peritonitis was increased by pressure. Referred pain often had a definite distribution, and might extend to the angle of the scapula or down over the crest of the ilium. There was no true cutaneous tenderness in peritonitis. The causes of pain peculiar to the right iliac fossa, in the order of their frequency, were disease of the appendix, perineal tuberculosis, and duodenal distension and adhesions. Those peculiar to the left iliac fossa were the referred pains from the malposition of the uterus and from the cancer of the sigmoid. Those causes that occurred with equal frequency in each iliac fossa were pus tubes and pelvic adhesions, ectopic pregnancy, dysmenorrhea, ovarian cyst with twisted pedicle, ureteral stone, localized tuberculous peritonitis, inguinal hernia, and the debility of neurotic, anemic women.

Dr. J. Watson Martindale of Camden in opening the discussion on the paper of Dr. Lee said that the author had gone so thoroughly into the physiological and anatomical conditions present that there was practically nothing more to say concerning them. He would, therefore, confine his remarks entirely to the clinical side of the subject. He said that pain was the most constant gynecologic symptom. It was more frequently noted in the lumbosacral or inguinal region. Spontaneous pain was usually produced by an acute lesion, while evoked pain was generally due to a lesion more or less chronic. Pain in pelvic lesions was commonly worse at night. The amount of pain was not always in proportion to the severity of the lesion. Many women suffering from large growths were comparatively free from pain; while, on the other hand, some of the more trivial conditions to which women were subject were often accompanied by very severe pain—for instance, dysmenorrhea. Another condition accompanied with severe pain was an acute flexion. This lasted until the uterus righted itself or was replaced. Cystic conditions of the ovary were not particularly painful. The pain accompanying acute salpingitis was spontaneous and very severe. Puerperal infection was often accompanied with severe pain in the milder cases, though many of the severe forms of this condition were not accompanied with much pain. In tubal pregnancy there was a period in which there was no pain. A woman might have a pair of pus tubes and enjoy comparative immunity from pain. While pain in the sacral and inguinal regions was generally suggestive of pelvic disease, a lesion in the groin was often productive of pain in the upper abdomen. It was a good plan in going over a patient suffering with pelvic or abdominal pains to look into the hernial orifices to see that there was no knuckle of gut caught and pinched.

Dr. Balleray had hoped that the meaning of the title of this paper was pain as a factor in the diagnosis of abdominal lesions, and wished that some one would write a paper on that subject and give some definite information regarding it. Pain located in certain regions of the

abdomen, he remarked, might mean one thing and when located in other regions might mean another. He quite agreed with the reader that some patients ran from one surgeon to another finding new conditions to be operated on, and surgeons ready to operate. If one could keep their minds off the pelvis it would be an advantage.

Dr. Elton S. Corson of Bridgeton said that the only diagnostician that he had ever seen who was able to put his finger on the location indicated by pain was an osteopath, and suggested the appointment of an osteopath to read a paper on this subject at the next meeting.

Calcium Sulphide.—Dr. John E. Pratt of Dumont said that there was a dearth of medical literature on the subject of the use of this drug as a prophylactic in infectious diseases. It was not strange, in view of the extreme variability of the drug and the facility with which, on exposure, it combined with oxygen to form different chemical compounds, that it lost caste with both physician and druggist. The failure to get results after repeated experiments by careful clinicians seemed to prove clearly and explicitly that the value with which the salt had been credited was a myth, and that the effects claimed to have accrued from its use were mere coincidences. Those who had retained a working element of faith in its therapeutic activity had urged a silent warfare against certain forms of disease, especially infections. In his own practice he had had occasion to use calcium sulphide in cases of scarlet fever to a considerable extent within the last two years. While he could not speak positively of its prophylactic virtue he could say that where it had been used in a family, among children that had been exposed to a case of scarlet fever already existing in one of its members, in no instance had a second child in the family been infected. The only child who had presented any complications during the two years of his employment of this drug in scarlet fever was a boy who had had the disease a week and whose sister before him had had it for two weeks without the cases having been reported or a physician having been called. This boy had otitis media, followed by mastoiditis.

Dr. Henry H. Sherk of Camden said that chemically pure calcium sulphide was prepared by heating calcium sulphate in hydrogen, or by heating calcium oxide in hydrogen sulphide gas. It was white, had an odor of hydrogen sulphide when moist, and was insoluble in water. It was phosphorescent in the dark. The reason that some did not get as good results from calcium sulphide as others did was on account of the impurity of the preparation.

Dr. Edward B. Rogers of Collingwood had used calcium sulphide, he thought, intelligently; had used it in full doses; and had employed the best preparation that he knew of. In his opinion it had been without any result whatever. He did not intend to give up trying it yet, because friends of his were getting results from it. He gave it in doses of one-sixth of a grain every hour, or one-third of a grain every two hours.

Dr. Horace L. Rose of Camden had many times obtained no results from the use of calcium sulphide; but when he secured a good preparation of it he thought that he did.

Dr. Hedges wished to ask Dr. Pratt what doses he gave calcium sulphide in, and whether he had the druggist make it up in the form of capsules or that of sugar-coated pills.

Dr. Pratt replied that he used granules, one-sixth of a grain every hour, usually, though he had given as much as a grain three times a day.

Certain Juxtajoint Fractures, and Certain Mechanical Principles in These Fractures.—Dr. Fred. H. Albee of New York City said that the limb should be put up in plaster in a position of strong flexion. This posture relaxed most of the strongest muscles. The longer fragment was put in accurate alignment with the position of the short fragment, and was held very securely. If limitation of motion at the shoulder occurred this relation of humerus to scapula was one of selection, both because it was a position of usefulness and also because it permitted the scapulo-thoracic muscles to functionate the most efficiently. The position was also more comfortable than one of extension.

Dr. F. D. Gray asked whether Dr. Albee, in the old classical fractures at the junction of the middle and upper or the middle and lower third of the femur, superseded the earlier double inclined plane by the plaster-of-Paris application.

Dr. Livengood of Elizabeth said that he saw more deformities from Colles' fracture of the wrist that had been set by competent surgeons than he did from any other fracture. He would like to have Dr. Albee's idea of the proper mode of repairing that fracture.

Dr. Albee in reply to Dr. Gray's question concerning the use of the double inclined plane said that he thought plaster was better. He believed that there was a perfect analogy between these fractures of the femur and the fractures of the shoulder that he had described, in which the long fragment was put in alignment with the position of the short fragment. In regard to Colles' fracture he used only the regular routine treatment that he had described. He thought that in many cases the trouble was caused by not etherizing the patient thoroughly enough to get muscular relaxation. The hand should be thoroughly and firmly extended and the displaced fragment brought into position. The hand should then be put up in plaster, with pads over the posterior and anterior sides of the reduced part.

Direct Transfusion of Blood: Its History and Probable Future—Author's Method.—Dr. A. L. Soresi of New York City said that transfusion had been well-nigh abandoned on account of numerous accidents that had happened during this procedure; such as hematuria, emboli, infarcts, etc. Besides, the advent of the isotonic salt solution made direct transfusion of the blood, in the minds of many surgeons, an absolutely useless procedure. This view was held by all the European surgeons, who never used transfusion now. The real dangers in transfusion of blood lay in hemolysis and blood clotting at the point of anastomosis. American surgeons deserved the credit of having discovered that to perform successfully a direct transfusion of blood the two intimas of the blood-vessels must be put in perect contact without traumatizing them. Transfusion was not a therapeutic means; it was only a procedure. It was the blood that was the therapeutic agent. Therefore this should be called hemotherapeutics. The methods devised for the transfusion of blood consisted in the suture method and mechanical devices. The former was very complicated, while mechanical devices made transfusion an easy procedure. Two methods, vein to vein and vein to artery, had been employed. Each should have its special indications. The future of hemotherapeutics lay in the possible discovery of means of avoiding hemolysis and being able to use, in this way, the blood of animals of different species. The method devised by the author differed from all the methods now in use; because the first step in the other methods (that is, cutting the blood-vessels) was the last in this. The instrument devised by him consisted of two hemicylinders. One end of each was encircled by some hooks. The two hemicylinders could be opened and closed at will, and were put and held together by a small bar and a screw. To perform transfusion it was necessary to isolate a blood-vessel for about three centimeters, open the instrument, insert the blood-vessel into the instrument, and cuff the blood-vessel over the hooks. When the two blood-vessels were in this way prepared they were cut close to the cylinder and the intima would in this way be inverted over the hooks. The two hemicylinders were put together and the

blood flowed from one blood-vessel to the other very freely, without danger of coagulation. It was necessary to isolate but one of the blood-vessels.

Dr. Gray said that the operation should be used only when there was occasion to replenish a decrease in the actual blood elements. Saline transfusion should be used in acute shock, where there was not a diminution in the blood elements, but a reduction in vascular tone. End-to-end anastomosis was difficult and tedious, and should not be considered, as mechanical devices had shortened the operation. The disadvantage of direct anastomosis, either by suture or by mechanical devices, was that it required close apposition of the arms of donor and donee. This strain on the vessels could be avoided by the free dissection of the vessels for an inch or an inch and a half. Dr. Gray thought that the best technique was the use of either the Elsberg or the Soresi instrument. It was very important, for the sake of the donee, to keep close watch of the condition of the circulation. The danger to the donee was acute cardiac dilatation. One should give plenty of blood, but not too much. Before beginning the procedure an accurate outline of the heart dullness should be traced on the chest of the donee. This should be checked up from time to time, and any increase of cardiac dullness should be a warning to suspend the process. It was not so difficult to get a willing donee in most cases as one would suppose.

Officers.—The annual meeting next year will probably be held at Spring Lake at the same time in June. The following officers were elected for the ensuing year: *President*, Dr. Daniel Strock of Camden; *First Vice-President*, Dr. Norton L. Wilson of Elizabeth; *Second Vice-President*, Dr. Enoch Hollingshead of Pemberton; *Third Vice-President*, Dr. Frank D. Gray of Jersey City; *Corresponding Secretary*, Dr. Harry A. Stout of Wenonah; *Recording Secretary*, Dr. William J. Chandler of South Orange; *Treasurer*, Dr. Archibald Mercer of Newark.

AMERICAN ASSOCIATION OF MEDICAL EXAMINERS.

Eleventh Annual Meeting, Held at Los Angeles, Cal., June 26 and 27, 1911.

(Special report to the Medical Record.)

(Concluded from page 54.)

Second Day—Tuesday, June 27.

Resolution.—It was moved, seconded, and carried that the Interstate Association of Medical Examiners sink its identity and become the Northwestern Section of the American Association of Medical Examiners.

Industrial Needs.—The industrial requirements which were contained in the President's address were discussed and it was decided that the time was inopportune for action, and that it would be inexpedient or unadvisable to take any action at this time.

The Early Diagnosis of Tuberculosis.—Dr. C. A. Shepard of Needles, Cal., read this paper. The French authorities had claimed that 90 per cent. of the cases of rectal fistula were of tuberculous origin. He did not think that they should rely upon such a statement in their insurance work. The tuberculin tests should be insisted upon in many cases. Was there any danger attached to this test? He did not think there was. Any physician could employ it if properly instructed in its use.

The Medical Examiner.—Dr. W. Ed. Grant of Louisville, Ky., presented this paper, which was read by Dr. G. Strohbach of Cincinnati. The foundation-stone of a successful insurance company depended upon the medical examiner; medical examiners who called themselves such and who became reckless fell short in their calling and compromised themselves. The importance of a proper understanding of the blanks upon which the reports were made to the companies was emphasized; this was not at all difficult if they only took the time to think them over. This saved the company much trouble.

Dr. Beckett thought that if they could get the medical examiners together at these meetings where they could listen to such papers as had been read before this association the blanks provided would be more fully filled out and much delay prevented. Many times he had to write and rewrite to a medical examiner in order to obtain certain facts which should have been made clear at the first examination. The medical director wanted a complete statement as to whether the applicant was insurable or not; had he a beginning tuberculosis; had he heart trouble, or some other condition which prevented his becoming insured?

Dr. Milton C. Conner of Middletown, N. Y., said that the medical director did not want the unimportant facts, but he did want facts upon which he could base an opinion as to whether the applicant would make a good risk or not.

The Use of Alcohol.—Dr. Allison Maxwell of Indianapolis, Ind., Medical Director State Life Insurance Company, discussed the question of the use of alcoholic liquors, one of the hardest questions the medical director was called upon to consider. Many applicants did not wish to answer the question properly; many times the examiner wished to shelter the applicant because of friendship or for other reasons. The very searching question was propounded: "If you use beverages of the alcoholic type, how much do you use in one day or in one week?" This was really a very hard question to answer properly. It was very important that they should get at the little details regarding the use of beer, wines, and other alcoholic beverages.

Dr. John Sidney Branch of Oakdale, La., said that it was difficult in many instances to get a satisfactory family history from the applicants, and particularly as to the use of alcoholic beverages. It was hard to get any accurate idea as to what amount of alcohol was consumed daily. He might not be what was called a "drinking man" but he frequently got more alcohol than he should get if he was to be a good insurance risk.

Health Conservation of Policy Holders.—Dr. Denslow Lewis of Chicago presented this paper, which was read by Dr. Stanton. A knowledge of the truth was the sure means of prevention and a conservation department had been recently established in New York. This movement was protective, and was of great benefit to the community. Bulletins were published regarding pure food, pure water, pure air, and the dangers of intemperance. The importance of correcting any deformities was emphasized, especially those of the nose and throat. The bulletins also told of the folly of accepting certain medicines as certain cures. The significance of aching pains was explained. First aid to the injured was taken up. Also the innocent way one could contract syphilis. The value of certain and definite hygienic measures was considered, all of which tended to the health conservation of policyholders. Venereal prophylaxis was also considered quite in detail.

Dr. Frank W. Foxworthy of Indianapolis, Ind., referred to the tubes that were used in the United States Army for the prevention of venereal diseases and the formula consisted of: Suet, 50; vaseline, 30; calomel, 20. This had not been successful in preventing venereal diseases. Dr. Foxworthy thought the day would come when the policyholder would be examined at regular intervals. There would also come inoculation of the various sera and vaccines for the prevention of disease among the policyholders. As the result of the injection of typhoid vaccines not a single case of the disease had appeared among 12,000 troops in San Antonio; yet in the town

where the vaccines were not used nine or ten cases had appeared. This showed the good that resulted from the antityphoid inoculations. There seemed to have occurred less reaction from these inoculations than from the use of the ordinary vaccines. When the day came when they would inoculate all the soldiers a great decrease would result in the mortality rate. Dr. Russell, who made the serum for use among the troops, stated that one dose was not sufficient, but that two doses should immunize the man against typhoid fever for life.

Dr. G. Strohbach of Cincinnati believed that this question of conserving the life of the policyholders by the life insurance companies was a very valuable and sensible undertaking, and that he had been contemplating a monthly publication which would take up health questions. The so-called "fad" side of health should be avoided; there should be taken up periodically in a sane and safe manner the way to have and to keep good health, food matters, clothing, and all other things that had to do with health. The various ways that food was being adulterated should be taught. Personally he believed in the movement under consideration and he felt positive that the leading sanitarians of the country would give their moral support to it.

Dr. Liston H. Montgomery of Chicago said that several months ago, during a conversation with a medical man in Chicago, one who had been in the United States Army, he obtained the following formula for use in the prevention of venereal diseases: Phenol, 3; calomel, 22; lanolin, 75. This formula was used among the United States troops about eleven years ago and the result nicely contrasted with the results given out by Belgium.

The Alcoholic Problem in Medical Examination.—Dr. Thomas D. Crothers of Hartford, Conn., presented this paper, which was read by title.

Arteriosclerosis—A Review of Cases.—Dr. Donald G. Frick of Los Angeles presented this paper, which was read by title.

Philadelphia Neurological Society.

At a stated meeting held April 28, 1911, Dr. Samuel Stern presented a communication entitled "Neurological Manifestations of Pellagra." He pointed out the relation that the ingestion of maize as food bears to the etiology of the disorder, and he dwelt upon the fact that the mental symptoms are rather to be looked upon as a complication, and accordingly they may exhibit wide diversity in both character and intensity. Dr. George E. Price demonstrated a patient presenting symptoms of "Cervical Pachymeningitis of Unusual Traumatic Origin." The case occurred in a colored man, 44 years old, employed in a steel works. In the course of his work he dislodged a flying splinter of steel, which struck him in the neck above the thyroid cartilage. There was pain with stiffness in the movements of the head. *X*-ray examination disclosed the presence of the fragment of steel in the deep tissues, and this was finally expelled in a paroxysm of cough. There had been some elevation of temperature, and it was believed that infection resulted, with extension to the cervical dura mater. Dr. Price reported "A Case of Unilateral Ascending Progressive Muscular Atrophy." The patient was an acrobat, who, following a sprain of the ankle, observed wasting and weakness of the corresponding lower extremity. He was soon able to resume his work. Seven years later, following a fall, it was found that the disorder had invaded the upper extremity on the same side, and it was now observed that there were fibrillary contractions in the affected muscles and that the knee-jerks were exaggerated. The opinion was expressed that the condition was one of chronic anterior poliomyelitis, with invasion of the lateral columns. Drs. M. H. Fussell and Samuel Leopold reported "A Case of Tumor of the Right Temporal Lobe Presenting Cerebellar Symptoms." The patient was a man who presented partial third-nerve palsy with ptosis and irritation in the distribution of the fifth nerve in association with paresis of the extremities on the opposite side of the body. Convulsions also occurred from time to time. There had been a history of headache. Further there was a tendency to fall backward. After death a tumor was found occupying the inferior aspect of the temporal lobe and exhibiting the histological characteristics of glioma. Drs. Wm. G. Spiller and C. J. Hunt presented a communication entitled "Extensive Spinal Epidural Endothelioma Causing Ascending Paralysis." The patient was a woman, who, following an acute infection of the chest, presented pain and weakness in the lower extremities gradually extending also to the upper extremities. The knee-jerks were enfeebled, but ankle clonus was present. After death an abscess-cavity of considerable size was found in the deep muscular structures of the back, and on the posterior surface of the dura mater, between the cervical and lumbar regions, there was an extensive new formation, which on histological examination presented the characteristics of endothelioma Drs. S. D. Ludlum and E. P. Corson-White presented a communication entitled "The Study of Heredity in Defective Children." Heredity they defined as the transmission of qualities from parent to child through the agency of chromosomes. As a result of their investigation they found that most of the conditions in defective children are acquired as a result of environmental influences, comprising, together with other things, morbid states of the parents resulting from toxic and nutritional states, syphilitic infection and the like. Dr. Andrew H. Woods read a paper entitled "Traumatism in Relation to Amyotrophic Lateral Sclerosis, with Two Cases." In the cases related, as well as in others studied, while there was an antecedent history of traumatism, there was reasonable room for doubt that this was the exciting factor. It seems not impossible that the condition arising from the nervous disease might be, in some instances at least, sufficient predisposing cause for the occurrence of the supposititious causative traumatism. Dr. Tom A. Williams presented a communication entitled "Psychogenic Quadrantic Hemianopsia by Simulation," relating the case of a pensioner who had made application for increased pension, and who apparently had loss of vision in one quadrant of the field. By tests, however, it was discovered that the loss of vision was simulated, and was due to voluntary suppression. Dr Williams also reported "A Case of Partial Hemianopsia and Partial Pituitary Syndrome," in which improvement followed treatment with the *x*-ray.

Dystocia Due to Echinococcus of the Female Pelvic Organs.—A. Bertino finds from statistics of the occurrence of echinococcus cysts in 2,785 cases that this complication is more frequent in women than in men, and that of the cases occurring in the pelvic organs more are found in women. They may occur in any part of the female genital organs; pararectal, paravaginal, paracervical, and paravesical, while they may invade the bones of the sacrum, the uterus, tubes, and ovaries. The effect of pregnancy and labor is bad. The increased blood supply of pregnancy causes the cysts to develop rapidly; when labor comes on they produce an obstacle to delivery, which has to be surmounted by an obstetrical operation. In some cases rupture of the cysts occurs during labor, allowing of the delivery of a living child. Out of 39 cases of pelvic cysts collected by the author 27 recovered and 11 died; of the children 16 were born alive and 19 dead (2 not recorded). The deaths in the mothers were from sepsis, rupture of the uterus, exhaustion, etc. When such a complication is diagnosed before labor operation should at once be performed to relieve the woman of the tumor.—*Annali di Ostetricia e Ginecologia.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

FUNKTIONELLE DIAGNOSTIK UND THERAPIE DER ERKRANKUNGEN DES HERZENS UND DER GEFÄSSE. By Prof. Dr. AUG. HOFFMANN. J. F. Bergmann, Publisher, Berlin.

ANALYSE DES HARNS. By A. ELLINGER, F. FALK, L. J. HENDERSON, F.N. SCHULZ, K. SPIRO and W. WIECHOWSKI. C. W. Kreidels, Publisher.

DER GEGENWÄRTIGE STAND DER PATHOLOGIE UND THERAPIE DER GALLENSTEINKRANKHEIT. By Dr. LUDWIG ARNSPERGER. 77 pages; paper; price 2.00 M. Carl Marhold, Publisher.

MODERN SURGICAL TECHNIQUE. By C. YELVERTON PEARSON, M.D., M.Dh., F.R.C.S. 484 pages; cloth; illustrated; price $4.00 net. William Wood & Company, Publishers, New York.

PLASTER OF PARIS AND HOW TO USE IT. By MARTIN W. WARE, M.D. Second edition; 99 pages; cloth; illustrated; price $1.25. Surgery Publishing Company, Publishers, New York.

GONORRHEA IN THE MALE. By Dr. ABR. L. WOLBARST. 175 pages; cloth; illustrated. The International Journal of Surgery Co., Publishers, New York.

AN INTRODUCTION TO DERMATOLOGY. By NORMAN WALKER, M.D., F.R.C.P. 338 pages; cloth; illustrated; price $4.00 net. William Wood & Company, Publishers, New York.

FOOD AND FEEDING IN HEALTH AND DISEASE. By CHALMERS WATSON, M.D., F.R.C.P.E. 638 pages; cloth; illustrated; price $4.00 net. William Wood & Company, Publishers, New York.

PRACTICAL CYSTOSCOPY. By PAUL M. PILCHER, A.M., M.D. 398 pages; cloth; illustrated; price $5.50 net. W. B. Saunders Company, Publishers, Philadelphia.

CLINICAL SYMPTOMATOLOGY. By ALOIS PICK and ADOLPH HECHT. 833 pages; cloth. D. Appleton & Company, Publishers, New York.

SOME NEGLECTED FACTORS IN EVOLUTION. By HENRY M. BERNARD, M.A., F.Z.S. 489 pages; cloth; illustrated; price $3.00. G. P. Putnam's Sons, Publishers, New York.

DISEASES OF INFANTS AND CHILDREN. By JOHN RUHRÄH, M.D. New third edition revised. 12mo; volume of 534 pages; illustrated; flexible leather; price $2.50 net. W. B. Saunders Company, Publishers, Philadelphia.

CHEMISTRY OF FOOD AND NUTRITION. By HENRY C. SHERMAN, Ph.D. 355 pages; cloth; price $1.50 net. The Macmillan Company, Publishers, New York.

WHAT TO EAT AND WHY. By G. CARROLL SMITH, M.D. 8vo; 310 pages; cloth; price $2.50 net. W. B. Saunders Company, Publishers, Philadelphia.

RADIOGRAPHIC ATLAS OF PATHOLOGIC CONDITIONS OF BONES AND JOINTS. By AMADÉE GRANGER, M.D. 206 pages; illustrated with 78 full-page half-tone plates; cloth; price $6.00 net. The A. L. Chatterton Co., Publishers, New York.

A WORKING MANUAL OF HIGH FREQUENCY CURRENTS. By NOBLE M. EBERHART, A.M., M.S., M.D. 303 pages; illustrated; cloth. New Medicine Publishing Co., Publishers, Chicago.

MENINGITIS, SINUS THROMBOSIS, AND ABSCESS OF THE BRAIN. By JOHN WYLLIE, M.D. 258 pages; cloth; price $3.00 net. Paul B. Hoeber, New York, Publisher.

FIRST AID IN NURSERY AILMENTS. By EVELYN LINCOLN COOLIDGE, M.D. 77 pages; cloth; price 50 cents net. Sturgis & Walton Co., Publishers, New York.

THE NERVOUS LIFE. By G. E. PARTRIDGE, Ph.D. 216 pages; cloth; price $5.00 net. Sturgis & Walton Co., Publishers, New York.

CRIMINAL MAN. By GINA LOMBROSO FERRERO. 322 pages; cloth; illustrated; price $2.00. G. P. Putnam's Sons, Publishers, New York.

DISEASES OF THE STOMACH AND INTESTINES. By BOARDMAN REED, M.D. 1037 pages; cloth; illustrated; price $5.00. E. B. Treat & Co., Publishers, New York.

TRATADO DE GINECOLOGIA. By Dr. MIGUEL A. FARGAS. Second Edition. Vol. I, 409 pages; Vol. II, 784 pages; paper; illustrated. Salvat & Co., Publishers, Barcelona, Spain.

RECHERCHES SUR LA MENINGITE CEREBROSPINALE. By ROBERT DEBRE. 120 pages; paper; illustrated. Felix Alcan, Publisher, Paris.

GEDENKREDE FRANZ KÖNIG. By Prof. Dr. OTTO HILDEBRAND. 10 pages; paper. August Hirschwald, Publisher, Berlin.

Medical Items.

A Special Complication of the Pasteur Treatment by Antirabic Vaccination.—C. Frogoni and C. Gargano direct our attention to a cutaneous effect of antirabic vaccination which is sometimes seen. This complication occurs from 20 to 25 times out of 400 to 500 cases treated by injections of antirabic vaccine. Soon after the injection there appears at the point of injection a sense of discomfort, the part becomes swollen, painful, and roughened, in a patch that is round or oval. The skin is hot, infiltrated, inelastic, adherent to the deep strata, and painful This goes on increasing for 24 hours; after 48 hours these phenomena have mostly passed away and there is itching of the region. This same condition is repeated after each injection; in some cases this causes the skin of the entire abdomen to become reddened, swollen, and painful. This condition never ends in suppuration or sepsis. There is never any fever. This effect was not caused in all the patients injected with a given specimen of serum. It is the result of a peculiar reactivity of certain individuals. It is possible that this phenomenon is one of anaphylaxis.—*Il Policlinico.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 28, 1911:

Places	Date	Cases	Deaths
Austria-Hungary: Trieste	July 23	1	1
Ceylon: Colombo	June 4–10	1	..
China: Kulangsu	June 17	..	1
Hoihow	June 2		Present
India: Calcutta	May 28–June 3	..	33

A DARWINIAN INTERPRETATION OF ANAPHYLAXIS.

By R. G. ECCLES, M.D.,

BROOKLYN, NEW YORK.

WHEN the discovery was made that the rubbing of a piece of amber (electrum) excited an unknown force which caused the electrum to attract to itself small pieces of paper and other light bodies no one had the slightest suspicion of the vastness of the range of the phenomenon to which the Anglicized Latin name—electricity, *i. e., ambericity*—had been applied. When Magendie, in 1839, "found that rabbits which had tolerated two (closely timed) intravenous injections of egg albumin without any injury whatever, immediately succumbed to a further injection made after a number of days,"[1] he was as little conscious of the great importance his discovery was destined to become for medical science. When doctors Salmon and Theobald Smith, on Feb. 20, 1886, presented to the Washington Biological Society the first paper ever written on the subject of vaccinating with the soluble proteins of bacteria it was not possible for them to foresee the momentous sequences that were soon to follow.[2] Behring, Kitasato, Roux, Ehrlich, and others, while pursuing the same route of research, have given us diphtheria antitoxin, serum therapy, and our knowledge of immunology. When Flexner, while experimenting along the route first blazed by Salmon and Theobald Smith, found in 1894 "that animals that had withstood one dose of dog's serum would succumb to a second dose, given after the lapse of some days or weeks, even when this dose was sublethal,"[3] it apparently did not dawn upon his mind that he was treading on the verge of a piece of phenomenon destined before long to open up a new era for medical science. Unhappily every important new development in human knowledge brings its martyrs. When Langerhans, in 1896, lost his two-year-old son—the first definitely recorded death following the use of serum—ignorance and wilful prejudice sought to attribute it to antitoxin. No one was yet sufficiently alert to see the great significance to humanity of the phenomenon that most likely was the direct cause of this pitiful sacrifice.[4] When Theobald Smith, in 1896, "was very much surprised to find that some of the guinea pigs which had been inoculated with heated bacilli, and in which there were no signs of active tuberculosis, after eight weeks succumbed promptly to small doses of tuberculin,"[5] he did not suspect that he was forging a new link to the chain of evidence that is rapidly carrying us toward a genuine science of medicine—a science crystallized around a single, uniting, definite, fundamental principle. When Portier and Richet, in 1902, injected into the veins of pigeons and dogs small amounts of a glycerin extract of the filaments of sea anemones (*Actinia*) and found that while first injections caused no harm second ones, containing no more, but given several days later, caused speedy death in animals of the same kind, although such animals could stand both doses if given together, without the slightest evidence of harm, there was still no suspicion of the deep significance of these results.[6] When, amid the public excitement aroused by the Langerhans' and a few other sporadic alien protein tragedies, Theobald Smith and his associates of the Massachusetts State Board of Health Antitoxin Laboratories found, prior to 1903, "that when guinea-pigs which had survived an injection with a mixture of diphtheria toxin and antitoxin" received a second dose some days later "they frequently died within a few hours," a new light began to dawn. When Professor Smith, in April, 1903, put into the hands of Dr. R. A. Lewis a record of some fragmentary experiments which he had made upon this strange phenomenon and supplied material and advice for a series of special experiments thereon,[7] the first move was made toward determining its meaning and consequences to mankind. When the same gentleman, in 1904, enlisted the interest of Ehrlich in this phenomenon, and when Ehrlich started Dr. R. Otto on another special investigation thereof, the second important move was made toward its definite solution. When our Public Health and Marine-Hospital Service, through doctors Rosenau and Anderson, in October, 1905, made certain experiments "in order to throw light upon the cause of this unfortunate accident" of death under antitoxic treatment,[8] a third step was taken in a direction which probably means very much more for life and health than even medical men can see. When Dr. Otto's report upon *"Das Theobald Smithsche phänomen der serum Ueberempfindlichkeit"* was published in Berlin in 1906[9] it opened a new page in medical history. It was the first publication of a special investigation devised for elucidating what has come to be known as anaphylaxis, allergy, serum sickness, hypersusceptibility, hypersensitiveness, etc. When Portier and Richet recorded their "hypnotoxin" experiments—experiments with *actinia* extract—as *"De l'action anaphylactique de certains venins,"* they evidently had no idea that they were dealing with other than a peculiar phenomenon of a peculiar poison. It did not dawn on their minds that it was a general protein reaction. Ehrlich, in giving the name "Theobald Smith phenomenon" to this anaphylaxis or allergy reaction, paid a gracious tribute to American medical science, for which we ought to feel thankful. We have the phenomenon of Arthus, the phenomenon of Kretz, the Bordet-Gengou phenomenon, Pfeiffer's phenomenon, Stohr's phenomenon, Babinski's phenomenon, Purkinje's phenomenon, Danysz's phenomenon, and others to act as incessant reminders that European

men of science are doing valuable biological work. Where is America's mark of honor? Ours is a pitiful blank in this galaxy. Since 1906 American work in anaphylactic research has been as great as that of any other country in the world, but unfortunately the busy men in the profession have not been able to give it deserved attention nor to bestow due honor on the thinkers and workers who have been promoting it.

A startling recent revelation is "that one-millionth of a cubic centimeter of a five per cent. solution" of a three times crystallized egg-albumin, "or *one-twentieth of a millionth of a gram of protein, will sensitize a guinea-pig* enough so that distinct and typical symptoms are produced after a second injection of the same material, while one fifty-thousandth of a cubic centimeter of solution containing but *one-millionth of a gram of protein sensitizes fatally.*"[10] Try and grasp the full significance of these words. Think of a grain of egg-white being divided into over 66,600 equal parts and one of these parts proving as deadly to a guinea-pig as a bullet through its heart. Strychnine and prussic acid are deadly, but they are almost harmless when compared with hen's egg protein administered intravenously after sensitization. We consume this deadly material with impunity as a constant article of diet. Friedberger tells us that "if into a guinea-pig a tenth of a milligram of the serum proteid of a sheep is injected subcutaneously, and if at a later period, as early as after ten days, five milligrams of the same proteid are injected into a vein, the animal goes into convulsions, has asphyxia, and dies."[11] His sheep's serum gave a lower toxicity than egg albumin, owing most likely to a difference in the toxicity of its molecules and to the less pure condition in which it was given. Gay and Adler found that "by fractional precipitation of horse serum with saturated ammonium sulphate precipitates are obtained which vary in their sensitizing and toxic properties. The first fraction is as highly sensitizing as whole horse serum, while the latter fractions are distinctly less sensitizing but more toxic than the first."[12] After years of work "in the study of cleavage products of proteins, bacterial, vegetable, and animal," Vaughan and associates report being able to split from more than thirty kinds, non-poisonous as well as poisonous proteins.[13] Wells declares that the "sensitizing and intoxicating effects have been produced with such extremely minute quantities of protein that it seems not unwarranted to maintain that these experiments settle this point conclusively. As a repeatedly recrystallized egg albumin, giving every evidence of chemical purity, is capable of causing sensitization in doses of one twenty-millionth of a gram, and of killing sensitized pigs in doses of one-twentieth of a milligram, it is evident that if either of these effects were due to something other than the egg albumin itself this contaminating substance must have a potency beyond the bounds of imagination."[14] The apparent discrepancy between the results of Vaughan and Wells are evidently due to the differences in their methods. The former, by cleaving his protein molecules would, if he left some intact, get just the results claimed, but on the other hand his claim that he splits all the molecules into haptophore and toxophore groups, if correct, would be a fair explanation. Those retaining the toxicity, by being weakened, would not be expected to give any greater poisoning power than did the intact molecules, and might not give as much. That such potency for evil should exist in them at all is remarkable, and it "cannot but excite our wonder that the chemistry of the body should be so delicately balanced that the introduction of 1/10,000,000 part of a gram of foreign protein should be able to so profoundly influence it as to result in serious symptoms when injected a second time."[15]. Most of this wonder centers in the fact that it is protein—our vitally essential food—that is so superlatively destructive. Nor is this poisonousness confined to animal proteins. The fact has been established that plant proteins have the same fatal power. Wells and Osborne have found that the sensitizing and intoxicating power of our common food grains is as great as those of the animal products. They tell us that "the sensitizing power of edestin (from hemp seed) is not noticeably less than that of crystallized egg albumin, as one ten-thousandth of a milligram (0.0000001 gm), the smallest sensitizing dose tried, rendered the guinea-pig sensitive to edestin. The intoxicating power of edestin is, however, much less than that of egg albumin."[16] The same authors tell us that "experiments have been performed with globulin from the castor bean (*Ricinus communis*), flax seed (*Cannabis sativa*), excelsin from the Brazil nut (*Bertholletia excelsa*), with proteins from the cocoanut (*Cocos nucifera*), legumin and vicellin from peas (*Pisum sativum*), legumin from the vetch (*Vichia sativa*), vignin from the cow pea (*Vigna sinensis*), glycinin from soy beans (*Sosja hispida*), gliadin from wheat flour (*Secale cereale*), hordein from barley flour (*Hordeum vulgare*), and zein from maize (*Zea mays*). It has been found that all of these proteins cause typical anaphylaxis reactions in sensitized animals, with all features essentially the same as when serum and other animal materials containing soluble proteins are used."[17] Whether plant proteins can injure alien plants as they do animals has not yet been determined, but it is evident that they do not injure the plants that produce them. Ehrlich's "horror autotoxicus" is here seen to extend to both kingdoms of living nature. The study of vegetable anaphylaxis is virgin soil that promises rich harvests in discovery to the botanists who take it up. The field is fallow and only awaits the husbandmen. What Hertwig tells us about the taking of grafts is early evidence of what may be expected. He asserts that "generally speaking, in the case of plants not adapted to each other, no attempt at union occurs, and the grafted twig speedily perishes, sometimes even the stem dies as if it had been poisoned by the graft."[18] If this is not anaphylaxis, then it would trouble an expert to distinguish between them. Since vegetable proteins as well as animal ones produce anaphylactic symptoms the evolutionist would expect, *a priori*, to find the bridging organic forms that lie between ourselves and these higher plants —the bacteria—also producing anaphylaxis. It, therefore, comes as no great surprise to them to learn from Prof. V. C. Vaughan that "egg-white contains the same poison, physiologically at least, as that found in the typhoid bacillus, and if egg-white could grow and multiply in the animal body it would, as a result of such growth and subsequent cleavage, be just as deadly as the bacillus of the infectious disease."[13] In essential confirmation of this are the experiments of Rosenau and Anderson, in which they secured pronounced anaphylaxis from injections into guinea-pigs of colon bacilli, yeast germs, hay bacilli, anthrax bacilli, tuberculosis bacilli, and typhoid germs.[19] Bergey, not long ago,

produced anaphylaxis with four common saprophytic bacteria.[20] Many others, both here and abroad, have had like results, so that it is now a settled fact that dead bacteria introduced into the body in spaced injections about ten days apart produce disease symptoms of a pronounced character. Lewis tells us that "the phenomenon of anaphylaxis with bacterial cultures responds exactly with the anaphylaxis to non-poisonous proteids, such as serum or egg-white," and then declares that "in order to assign the phenomenon of anaphylaxis in the narrower sense a fundamental place in the immunity to disease of the type of typhoid fever, cholera, or the septicemias, the localized diseases due to micrococci, it would seem necessary to assume that the disease is due to the bacterial product as such."[21] In agreement with this Von Pirquet attributes the symptoms of vaccinia, smallpox, glanders, actinomycosis, lepra, syphilis and other diseases to anaphylaxis.[22] In disease symptoms there is a sameness attached to all, together with the particular symptoms characteristic of the given pathogenic organism. In anaphylaxis from food proteins the same is the case. Wells tells us that "it is possible to tell with assurance whether a reaction is being produced with egg-white, which causes highly irritative effects, or with serum, which causes more paralytic symptoms."[23] There is, likewise, the same specificity to food-protein anaphylaxis as is seen in disease. "A guinea-pig," says Rosenau and Anderson, "may be sensitized with egg-white, milk, and horse serum, and subsequently react in a brief period of time to a second injection of each of these substances"; and they add, "the guinea-pig differentiates each anaphylactic-producing protein in a perfectly distinct and separate manner. The animal acts as though susceptible to three separate infectious diseases."[24] A list of anaphylactic symptoms, produced by, say, a dozen different food proteins, would include every prominent symptom of the diseases we are familiar with, from chill and fever to inflammation and death. Is it then not quite probable that typhoid fever, diphtheria, scarlet fever, measles, meningitis, yellow fever, malaria, pneumonia, consumption, and the many other diseases with which physicians are familiar, may be but the specific anaphylactic reactions of the proteins of the respective parasites? Moschcowitz recently pointed out that asthma, hay fever, urticaria, skin diseases characterized by exudative lesions, eclampsia, pellagra, goiter, tetany, migraine, and epilepsy give indications of being due to anaphylaxis. Others before him referred to many of these as probably having such an origin, but he has added the observation that they are all associated with eosinophilia and that "the invasion of eosinophiles in increased numbers into the organism is the expression of an active agent or the agent itself in the production of anaphylaxis."[25] "In hook-worm disease," says Ward, "the main feature of the blood is an eosinophilia, both relative and absolute,"[26] and "one of the most characteristic features of the animal parasites," says Wells, "is that they exert a positive chemotaxis, particularly for eosinophile leucocytes."[27] It thus seems that at last we are on the track of an all-embracing principle with which to link medical facts together, rationally, as in the well advanced inductive sciences. Such a view as this, if established, is certain to revolutionize medicine as completely as the inductive sciences have been revolutionized during the last century, and for the same reason. "The discovery of new facts," says Bancroft, "makes a subject more complex and more difficult to grasp. The discovery of new relations simplifies matters because it enables us to get a better grasp of the subject."[28] This relating of all medical phenomena under a common principle will simplify medicine for its students to such an extent that it will literally introduce a new era.

On considering how tremendously toxic to sensitized animals alien proteins are we are constrained to ask ourselves what it means. Why should our one essential life-sustaining substance always appear as a veritable Azrael? Why require protective devices to save ourselves from its awful destructiveness? There is certainly nothing of selective value to the consumer in such deadliness. To him it is an ever-present menace—a diabolic mal-adaptation—a sort of sword of Damocles, constantly threatening destruction. "Natural selection," says Darwin, "will never produce in a being anything injurious to itself,"[29] and in agreement with this obvious implication of his doctrine we find that it is invariably *alien protein* that injures. The animal's own proteins, as well as the proteins from members of its own species, are harmless. Is there not weighty evidence of some sort of systematic selecting or sifting discernible in the fact that all plants and all animals produce proteins perfectly safe for themselves and close of kin, yet deadly to their marauding foes? Mere chance could never have made so perfectly even a distribution. It has every appearance of either purposefulness or selection. But if it is purposeful why has it been directed so completely against man? Every particle of protein food we consume is alien protein and carries with it a threat of death. Only by becoming cannibals could we escape the ever-constant menace. What sort of beneficent purpose can be subserved by thus placing a penalty on the consumption of such food as we are compelled to use, and a premium on cannibalism? In the struggle for protein food that always exists between the plant or animal that produces and the man or beast that consumes there is ample evidence of selective value. Any change in the protein that can make it safe for its producing owner and dangerous for its consuming foe helps the owner in its battle for life. If every particle of protein in the world could be suddenly transmuted into harmless, homologous protein would it be long before the fight for possession would convert it back into toxic protein again? Granted that it would vary, as all things do, and that the variations would occur in all possible directions, then some of it would vary toward poisonousness. Such a variation would instantly give the advantage to the organism in which it occurred as against all other organisms. If the toxicity should suddenly become great it would quickly exterminate every animal that tried to consume it. If it occurred slowly and by degrees then there would be time for protective variations to arise in the consumers. They would hold each other at bay to just such a degree as would permit of both living. It appears to the writer that if under existing conditions the transmutation referred to should happen it would not be cosmically long before all alien proteins would regain their toxicity through natural selection. Every known biological condition tends in that direction. On the other hand, the consumers must vary protectionward. Since all alien proteins are dangerous and since only alien proteins are available as food, it necessarily follows that all consumers of alien proteins must acquire means of

overcoming the toxicity or perish from the earth. It thus happens that all have some degree of protection against most proteins and a small degree against deadly toxins. Remove the protective devices, as in the production of anaphylaxis, and all become equally deadly, or nearly so. The reason why tetanus and diphtheria toxins are so much more deadly toward us than is beefsteak or egg-white is that our barriers against the latter are more perfect than against the former. Remove the barriers by sensitization toward the latter and then compare the figures of their respective toxicities. If beefsteak and egg-white could reach the life centers of our cells as completely and as rapidly as the toxins do, what reason have we for believing that they would prove less destructive? Both lose their toxicity by being digested. Both have their toxicities heightened by sensitization. Both produce in the cells after successive doses a heightened resistance. Both give indications of a protein nature. We have little or no immunity of toxins because we and our progenitors have not been fed for many ages upon them, as we have upon beefsteak and egg-white. The particular cells for which the toxins have an affinity have not built up protective mechanisms against them as have the cells for which the steak and eggs have their affinities. The digesting enzymes used in the destruction of the last named can because of generations of adaptation destroy their deadly qualities quickly and effectually, while no such perfect adjustment for the speedy destruction of the toxins has been selected. Existing meat-eating and egg-eating animals are here to-day because all of their species that failed to make such adaptations disappeared long ago from the planet. The intestine in each individual now "forms a solid barrier between the heterologous compounds in the food and the homogenous building material for the blood and tissues, the composition of which has been established by the entire development of the given animal species."[30] Thus it happens that "the whole problem of protein metabolism seems to be an adjustment in the sense of a defense," for "the power to assimilate and use foreign proteins is not achieved without a certain amount of violence to the body."[31] Thus it is that when anaphylactic experiments are conducted in conjunction with digestion experiments it is always found that the anaphylactic symptoms depend "upon some constituent of the serum that decreases *pari passu* with the coagulable protein," that "peptic digestion of egg albumin destroys its power to intoxicate sensitized guinea-pigs only when it has destroyed practically all coagulable protein," that "for the anaphylaxis reaction we must have intact protein molecules,"[32] and that "digestion with trypsin gradually destroys the sensitizing and intoxicating principles."[33] It is because of protein toxicity, if Darwinian deductions coupled with the test of research-discovery as a check can be relied upon, that our digestive organs have developed to what they are. The data of paleontology, embryology, and comparative physiology, already in our possession, lead to the conclusion that if we could secure a complete panorama of the successive steps which have led to the production of our present digestive mechanism it would probably show, (*a*) a time on our planet when only monocellular forms of life existed, and that then each cell captured, destroyed, and digested its own prey; (*b*) a time when differentiation produced cells having a phagocytic function that made them the chief agents in capturing and destroying the prey for their associated fellow cells;[34] (*c*) a time when a surface sulcus, developed into a gastrula where prey could be trapped, rendered harmless, and in a partially digested condition carried to the cells;[35] (*d*) a time when the gastrula deepened into forming an intestine that better enabled the owner to evacuate waste materials;[36] (*e*) a time when some cells of the intestine developed into glands that secreted digestive enzymes and poison-neutralizing substances;[37] (*f*) and, finally, a time when this primitive liver-pancreas divided its functions, giving us pancreatic, peptic, Brunnerian, hepatic, and like glands as distinct organs.[38] Every one of these steps seems to have had as its chief, if not its sole, purpose the saving of the internal cells from anaphylactic and other toxic means of destruction. To such medical men as entertain any remnant of the old exploded doctrine that the digestive organs exist for the purpose of putting our food into solution, so that it can be absorbed by the tissues, this statement will appear to be nonsensical. They should get a mental grasp of the newer physiology. Let them consider the facts of the next paragraph.

Before it was discovered that the getting of proteins into perfect solution did not properly fit them for cell assimilation our notions of the true function of digestion were exceedingly hazy. The belief that "the 'purpose' of the splitting of protein in the intestines" was merely "to make it soluble and capable of being absorbed," is now a thing of the past.[39] Chittenden declares that "it is difficult to see why if digestive proteolysis has for its sole object the conversion of the proteid foods into forms suitable for absorption there should be any considerable breaking down of protein beyond the proteose or peptone stage, since the latter bodies would seem to be most easily adaptable for transportation into the proteins of blood, lymph, and tissue."[40] With the food digested into perfectly soluble condition, as proteoses and peptones, why should it be torn down into the much smaller amino-acid shreds? These acids do not, as such, appear in any appreciable amounts in the circulation. The blood is not a stream of dissolved amino-acids. In it they are all found *reconverted into protein again*. What is the meaning of such a reconversion following immediately after the destruction of the original protein? Why is it that our bodies after going to the trouble of destroying almost every shred of the food proteins takes "from the common protein, typified by serum albumin," instead of from the products of digestion, the material with which to form "the specialized body proteins?"[41] All of the work of tryptic and erepsin digestion is, if the old notions of digestion are true, utterly wasted. Of what conceivable use to the body, according to that view, could such digesting be when every particle of it has to be, to all appearances, undone? Think of a man tearing down a house merely for the fun of having to rebuild it again. So bungling an arrangement is certainly far from economical. From the viewpoint of either natural selection or purpose the whole matter looks absurd. The doing of work that needlessly increases the labor of the body could have no selective value—could save no lives. Natural selection could not select wastefulness, nor can we imagine beneficent foresight tolerating it. If the molecules of alien proteins are dangerous in their structures toward the protein molecules of consuming organisms, then we can readily see why the whole molecule should be torn asunder and rebuilt

after the pattern of that organism. There is no mystery in that, and it contains positive evidence of being of selective value. If a death menace hangs over the consumer that fails to tear every molecule into its final physiological fragments, and if this menace has always hung over the race, it is easy to see exactly why the entire intestine and its complex digestive apparatus slowly evolved along the route to which reference has been made. Every successive step, by giving an advantage in the struggle for existence to its possessor, allowed that possessor to live and multiply its kind, while those not thus favored must have perished. Step by step gains were made on one side, while step by step poisonousness increased on the other. That which was at first developed as a poison ceased to act as such because the protective mechanism destroyed its power to kill. Thus, in spite of increasing toxicity, no such increase was observable. The poison of to-day became the food of to-morrow. Indeed, its triple deadliness, on the removal of the protective devices, is probably due to its food qualities, since as a food it would be chemotaxic for the cell receptors of food, and deadly because of being unadapted in size or form for fitting into the cell molecules. It would, like a crowbar thrust between the cogs of a swift-moving machine, bring wreckage. A study of the structures of some protein molecules will make the matter clearer. The following five, viz., casein, ovalbumin, muscle, zein, and gliadin, give the amino-acid composition of each to the extent of 12 of their acids. As can be seen by the percentage figures, none of them are complete. They lack from about 20 to 50 per cent. of their totals.

		Milk Casein.	Egg Ovalbumin.	Chicken Muscle.	Maize Zein.	Wheat Gliadin.
1	Glycocoll	0.00	0.00	0.68	0.00	0.02
2	Alanin	0.09	2.22	2.28	9.79	2.00
3	Valin	1.00	2.50	....	1.88	0.21
4	Leucin	10.50	10.71	11.19	19.55	5.61
5	Aspartic acid	1.20	2.20	3.21	1.71	0.58
6	Glutamic acid	10.70	9.10	16.48	26.17	37.33
7	Lysin	5.80	3.76	7.24	0.00	0.00
8	Arginin	4.84	4.91	6.50	1.55	3.16
9	Histidin	2.59	1.71	2.47	0.82	0.61
10	Prolin	3.10	3.56	4.74	9.04	7.06
11	Phenylalanin	3.20	5.07	3.53	6.55	2.35
12	TYROSIN	4.50	1.77	2.16	3.55	1.20
	Total %	47.52	47.51	60.48	80.61	60.13
	Missing %	52.48	52.49	39.52	19.39	39.87
		100.00 (42)	100.00 (43)	100.00 (44)	100.00 (45)	100.00 (42)

In considering the figures of this table the reader should particularly note that any single one of the five proteins named at the top contains in one of its molecules one, two, three, or more of the twelve amino-acids given. Imagine the sections of an orange and each section will represent one of these amino-acids, while the whole orange represents the protein molecule. If the various sections of the orange differed in color or shape and it was large enough to contain, say, twenty or thirty sections, the resemblance would be the greater. In one single molecule of casein, for instance, there are building sections in its structure of alanin, valin, leucin, aspartic acid, glutamic acid, lysin, arginin, histidin, prolin, phenylalanin, and tyrosin radicals all clinging together as a single chemical unit. As our analysis shows less than 50 per cent. of its total contents, supposing there are only one of each of the twelve radicals named, then it only shows about one-half of the real size of the casein molecule. But since it is known that there are many more than one molecule of glutamic acid and of leucin in a single molecule of casein the size must be very much greater. Lusk says that "the chains of amino-acids forming this complex must be of (relatively) immense size to comprise the many and varied elements set forth above. Osborne calculates the molecular weight of protein at 15,000 or some higher multiple of this."[46] A molecule of casein is not less in weight than 15,000 atoms of hydrogen, but it may be equal to 30,000, as chemical methods of calculating such things can only give multiples of the minimum. Relatively immense as such molecules are when compared with hydrogen atoms they are exceedingly small as compared with the size of a leucocyte, which is most likely made up of hundreds of thousands of these protein molecules. It is out of relatively small cells that we are made, out of relatively small protein molecules that cells are made, and out of relatively small amino-acid radicals that protein molecules are made. The analysis shows that wheat gliadin contains 60.13 per cent. of its weight, minus a minute amount of water of hydrolyzation, in the twelve amino-acids named, while zein from Indian corn has over 80 per cent. of its structure accounted for by these. Of the missing constituents only 19.39 per cent. were lost in analyzing zein, while 39.87 per cent. could not be crystallized out of gliadin. Milk casein shows 52.48 per cent. missing, or nearly three times as much as does zein. As the figures represent many analyses of each, the missing elements are peculiar to each particular protein. Now observe some of the differences in the amounts of the acids common to each. Gliadin, as it exists in bread, has less than half as much phenylalanin as exists in ovalbumin, while the ovalbumin has only about one-fourth the amount of glutamic acid that exists in the gliadin. In no two of the five proteins do the ratios of their respective amino-acids agree. When the digestive organs of a chicken undertake to convert wheat gliadin into food for chicken muscle what must occur? The gliadin contains 37.33 per cent. of glutamic acid, but the muscle only needs 16.48 per cent. There is 5.61 per cent. of leucin, but the muscle must have 11.19 per cent. To get the 5.61 per cent. up to 11.19 per cent. over twice as much gliadin would have to be destroyed than is needed. There is 7.06 per cent. of prolin and only 4.74 per cent. needed. There is not a trace of lysin, yet chicken muscle demands 7.24 per cent. We can see in this why a mixed diet is imperative. With only 0.61 of histidin there is a demand for 2.47 per cent. Four molecules of gliadin must be destroyed in order to get out of it the needed amount of histidin for a single molecule of muscle protein. If the chicken adopts for its diet wheat gliadin and corn zein, since neither contains lysin there is likely to be a longing void for something, it knows not what, felt within its stomach. Distribute the amino-acids of alien proteins as we choose and there must be a surplus of several kinds that are unavailable for assimilation as amino-acids and that must be disposed of by the body. As with the chicken, so with ourselves. We must rend zein, gliadin, and all other available protein molecules asunder so as to be able to sift the amino-acid products into useful and, until further broken up, useless fractions. The unused surplus is disposed of by being destroyed by having its nitrogen "split off in the form of ammonia, and this ammonia, uniting with carbon dioxide, is carried as ammonium carbonate to the liver and there synthetized as urea."[46] Because of

this, "ammonia is found in considerable amount in the portal vein after a meal, but is normally screened from the general circulation by chemical changes in the liver,"[47] while "the portal blood during digestion contains four times as much ammonia as arterial blood."[48] Such amino-acids as tyrosin, phenylalanin, tryptophane, and cystin as are in excess of the body's needs become food for bacteria. The bacteria digest away from them all the available elements, leaving the indigestible parts unconsumed, as phenol, paracresol, indol, skatol, sulphurous acid, sulphureted hydrogen, and other malodorous constituents of feces.[49] The reader should note at this point that the food and not the bacteria contain the radicals that become such poisonous substances. They preexist as pro-poisons in the food. The bacteria leave them because of being unable to digest them. They are generally more poisonous for the bacteria than for us. Natural selection never can produce anything in an organism that is injurious to that organism. The plants and animals that produced the proteins placed these poisons in them and the bacteria being endangered by them leave them in our intestinal tracts unconsumed. There are still other pro-poisons in ordinary food that deserve attention here, but the descriptions of which would make this paper too long. Among these we may mention the cholins, the purins, pyramidin, and the amino-acids that on bacterial destruction leave behind putrescin, cadaverin, and isoamylamin. Some cholins are very poisonous, and the purins are the source of uric acid.

Theories of the cause of anaphylaxis are numerous, but none of those heretofore advanced have tried to trace the subject out as a fraction of the larger problem of organic evolution. This is probably the first attempt of the kind ever made. That anaphylaxis is due somehow to alien proteins is conceded by all. That its specificity follows the path along which species have been produced has been proven by experiments. Von Pirquet declares that "the power of a given serum to produce anaphylactic symptoms corresponded absolutely with the intensity of the precipitin reaction,"[50] and Schryver tells us that "the more nearly allied the species to that from which the precipitinogen has been derived the more readily will its protein give a precipitate with the precipitin."[51] This specificity of the precipitin agrees with the species of the animal and the anaphylactic manifestations follow exactly the same path. Wells declares that "the question of specificity stands up as a sphynx-like obstacle that has so far not been passed,"[52] and an evolutionist could hardly expect it to be passed until such times as its students brought it into logical harmony with the power that directs the formation of species—the power of natural selection. The proteins (the precipitinogens) that all acknowledge to be the cause of the production of precipitins have a specific structure. This structure is due to their being chiefly built up of definite amino-acids, definitely arranged, in definite proportions. Abderhalden assures us that "in the formation of proteins the amino-acids alone participate as far as we know, with the single exception of the amino hexose glucosamin."[53] As the specific structures of the proteins are due to their amino-acid content and arrangement, why should we not infer that the specificity of the phenomena produced by them is due to their chemical natures that are due in turn to the amino-acids? Experiments have shown that alien proteins in which the amino-acid contents have been disturbed in their relations refuse to produce specific results either in precipitins or in anaphylaxis. Reagents that destroy the aromatic amino-acids, tyrosin and tryptophane destroy thereby the specificity.[54] Remove these same amino-acids by digestion and the proteose fragments display no specificity.[55] In connection with this let us consider the exceedingly significant fact that these very amino-acids—tyrosin and trytophane—are among the pro-poisons of the body to which reference has been made. But there is a third amino-acid that is likewise a pro-poison, and that is one of the early ones to be removed by digestion. It goes by the name of cystin, and is, like the other two, mostly removed from proteoses that refuse to produce specific precipitins and specific anaphylaxis.[56] When a house is being torn down piecemeal the last row of bricks placed upon the walls by the builders is the first row to be removed by the unbuilders. The fact that the three pro-poisons, cystin, tryptophane, and tyrosin, are always among the first to be removed in digestion indicates that they were the last to take their places upon the protein molecule. Digestion is a reverse process to growth. The fact, too, that specific precipitins are producible for all sorts of animal proteins indicates that these amino-acid pro-poisons are under constant change with every change of species. In no other way could we imagine their controlling specificity. If as pro-poisons they are to be of any advantage to their possessors in the digestion struggle of cell with cell they should be found where required at the point of splitting of the molecule, they should be easily detachable from the molecule, they should be perfectly harmless when unattacked by consuming enemies, and they should be ready to produce deadly results on release. These conditions seem to be all present if the facts are fairly interpreted. In singular confirmation of our interpretation stands the exceedingly remarkable fact that our skins and nerve-sheaths—the tissues most exposed to parasitic attack and the tissues that shield the most vulnerable portions of the body from parasitic attack—are the very tissues that contain the largest proportions of these amino-acid pro-poisons of any other part of the body. The hair and claws, that share with the skin the rôle of defense in the lower animals, share also in this identical protection. It has been pointed out by Partier that "oxidases are concentrated in the epidermal and exposed structures of the organism (where they can oxidize the sulphur of the cystin when attacked). He is of the opinion, therefore, that their physiological rôle both in animals and plants is one of defense against invasion by micro-organisms."[57] If used as a defense in these tissues why may they not be deemed of use in defense in the other molecules of the body? As will appear later, they can become efficient agents in destroying aggression by digestion. In order to understand something about how they act we must consider how they are attacked. In all digesting it has been found that three substances are always concerned. In stomach digesting we have: (*a*) the protein, as meat, fish, egg, etc., to be digested; (*b*) the hydrochloric acid that converts the protein into an electrolyte by neutralizing part or all of the alkalinity of the protein, without which neutralizing it cannot be digested; (*c*) the enzyme called pepsin that in some manner directs the hydrogen and hydroxyl ions so as to split the protein molecule. The conditions of intracellular digestion differ in some particulars

from stomach digestion. Ehrlich's work has given us facts that clear up this form of digestion very much. He has shown us that there are here likewise three substances concerned. These are: (*a*) the protein to be digested, such as other cells, bacteria, protozoa, or, as in anaphylactic, precipitin, and cytolytic work, such antigens as serum, egg-white, gliadin, etc.; (*b*) the substances that convert the protein that has to be digested into an electrolyte and that go by the names of antibodies, interbodies, immune bodies, and amboceptors; (*c*) the enzymes variously known as addiment, complement, alexin, etc., that direct the hydrogen and hydroxyl ions to the point of scission in the alien protein. Intracellular digestion seems usually to resemble trypsin rather than pepsin digestion in that the protein to be digested is converted into a basic and not an acid electrolyte. The point of greatest logical importance for the purpose of this discussion is the fact that "it is the amboceptor alone that gives the specific nature to the reaction."[58] Much confusion has arisen in the minds of many by not separating this function of the amboceptor from the functions of the complement (enzyme). Through Ehrlich and Morgenroth's work we have learned that the "body in an immune serum which we term the amboceptor can in one and the same animal be shown experimentally to be made up of a host of different kinds of amboceptors."[59] Arrhenius tells us that "Ehrlich supposes that all possible antibodies (amboceptors) exist in normal sera."[60] If every possible amboceptor or antibody for all the millions of various kinds of alien proteins exists in normal blood, as Ehrlich declares, and if every one of these millions is specific for the particular protein introduced, it logically follows that either the amboceptors are combinations of a few elementary substances capable of being linked together into these millions of intricate fitting specific forms, or every injection of protein into an animal's veins results in a miracle more wonderful than any that credulity ever believed. If, like the letters of the alphabet in a printer's case of type, a few substances are linkable into these myriads of combinations, then the matter is comprehensible, but otherwise not. A printer can copy any one of millions of unlike printed pages, matching them with exactitude, and only use the twenty-six letters of the alphabet, a few spaces and a few stops. Now we come face to face with another most remarkable fact. Recent biochemical research has demonstrated the fact that blood serum and cell proteins are composed of just the kind of substances that are capable of building themselves together in this specific manner. These substances are the amino-acids and their polypeptid combinations. Their linkages can be infinite. Nothing else known in organisms can be suspected of having such qualities as will meet the requirements of Ehrlich's amboceptors. A study of alien proteins shows that they are built just as they should be to be able to produce the millions of specific amboceptors needed to convert them into electrolytes. We learn from Mann and others that these molecules are at one and the same time polyacid bases and polybasic acids.[61] They will not digest until either the basic or else the acid charges are suppressed and they have thus become electrolytes. Taking egg-albumin as a sample of all proteins we discover that it is a 35 acid base, *i. e.*, has 35 carboxyl bonds to bind before it will leave perfectly free its amino-bonds for hydrolysis.[62] When we stop to consider the fact that no two proteins have the same ratio nor the same distribution of their amino-acids, we are forced to conclude that the distribution of the 35 or more uncondensed carboxyl bonds must vary in their distribution upon the molecules of different proteins. It is entirely unlikely, in view of such facts, that the distribution upon the molecules of an eagle's albumin will be just the same as upon those of a hen's albumin. We would also expect the difference to be greater in an amphibian's egg than between any two bird's eggs. Each will have a distribution giving a mosaic or pattern of its own. In neutralizing these respective mosaics of, say, the albumins of hen, eagle, and crocodile, the linked amino-acids that neutralize them must form a cast-like reverse image. A printer's form of type produces a printed page on paper that is a mirror image of his metal type. The cast of egg-albumin (its antibody) which the blood produces is a minute representative of a printed page, while the protein represents the metal types that are copied. In intracellular digestion the flow of the protoplasmic stream around the alien protein molecules, by giving up the required amino-acid side-chains that fitted the mosaic, would build the cast into specificity, although the materials used would be wholly unspecific. Let an excess be formed and let them racemise, by the formation of anti-antibodies—forms that are actually produced—and all the conditions of immune sera would exist. By having antibodies and anti-antibodies conjugated, as in the molecules of racemic acid, a supply of antibodies could be maintained in the circulation for a long time. The linking together of the amino-acids to form antibodies (polypeptids) would occur through reversed enzyme action, as in the building of proteins. The known fact that our cells use glycocoll—an amino-acid—for the purpose of closing the carboxyl bonds of benzoic and salicylic acids, thus producing hippuric and salicyluric acids, is evidence that it is a habit of the body to dispose of such bonds in this manner. If single carboxyl bonds are conjugated in this way why should not a group of 35 or more such bonds on a molecule receive similar treatment? Since most cells contain all known physiological amino-acids there can be no theoretic objection urged against the acceptance of such a view as a good working hypothesis, and thus looking upon the amboceptors as linked polypeptids of definite patterns. This would give us a reasonable explanation of the specificity of precipitins, hemolysins, cytolysins, bacteriolysins, and anaphylaxis, corresponding exactly with the known chemical facts. It introduces nothing mysterious or unusual, but deals only with conclusions that are verifiable if true and refutable if false. It already links every phase of immunochemistry into a coherent and harmonious whole. It can add greatly to the heuristic value of Ehrlich's "*Seitenkettenthcorie*" (side-chain theory), but by transferring the chains to the protein molecules instead of the cells. The cells, as such, are complex machines and not chemical entities, as some have been led to believe. They are immensely larger than molecules. Professor Adami, in his new work on pathology, presents a view of this kind.

If anaphylaxis is due to an effort of the cells to digest more alien protein than they can care for the toxic products of, we must infer that some damage is done to the cells even in the sensitizing stage. The abnormal strain should be expected to leave some more or less permanent effect. A cut

will leave a scar for life, and if healing is delayed will shed serum for a long time. Any slight injury to the lachrymal glands will on the slightest provocation cause an involuntary flow of tears, the easy repetition of which may persist for years. Catarrhal discharges follow bacterial invasions of mucous membranes, and when the enemy is not wholly dislodged will become chronic. We ought, therefore, to expect that anaphylaxis will leave more or less permanent effects upon the cells. In the forced overproduction of receptor side-chains for the construction of antibodies the current of the cell's life must be strained and altered, sometimes seriously. Analogy would lead us to expect a continuance of the production of such antibodies even after the protein that evoked them had all disappeared. If only a few of the wrongly linked amino-acids of the alien protein could not be dislodged from connection with cell receptors and could not be destroyed we should expect a long continued flow of cell receptors making in this way a fruitless effort at removing them. Weigert refers to this habit of excessive production as a biological law. Ehrlich approves of this view, but Arrhenius asserts that as a law it has no scientific standing.[64]. Such a habit, however, under the conditions named would have great selective value and has the support of analogy. The long continuance of quick anaphylactic response to alien proteins and the speedy occurrence of severe shock are evidences of a persisting abnormal condition of easily evoked irritability. The presence in the circulation of ready-formed antibodies, due to the flow of protective receptors from points of slight injury upon the cell molecules, enables the cell to ward off the more easily further injury of the same kind when a fresh supply of alien protein enters the blood. But a counter selection from the other side undoes all this. The same law of natural selection that gave the cells their antibodies gave the alien proteins their power to thwart these antibodies. Given more alien proteins than there are antibodies and complements to digest them and there is once more trouble for the irritated cells. Given the speedy digestion of these proteins and the rapidly released pro-poison acts as another stroke of fitness for the invader. It is check and counter-check at every turn along the road of progress. As soon as the antibodies convert the alien protein molecules into electrolytes, and the complement adheres, the amino-acid pro-poisons are set free in their nascency, ready to link themselves to the cell receptors. Here are discernible the tactics of war, the tactics, too, of natural selection. On one side we can see the means of protection and on the other methods of overcoming that protection, as the next move in a desperate game. The antibody is protective, but an overmultiplication of antigen (bacteria, protozoa, alien protein, etc.) more than counterbalances. The complement also protects by digesting the antigen, but this releases the unassimilable excess of pro-poison amino-acids, thus overcoming the benefit. The oxidizing enzymes seek to destroy the blockade of unassimilable material only to release the active poisons which the latter carries. This they destroy unless in excess, in which case the victory goes to the invader. But there is a leading trick in the game. It is discoverable by a study of the precipitin reaction. In order to obtain any sort of conception of how specific precipitins might be produced we are compelled to assume that *pari passu* with the evolution of species in plants and animals there has been a continuous shifting of the places where the pro-poison amino-acids are anchored upon the protein molecules. Let the cells acquire the ability of saving themselves from injury by becoming able to split the alien molecule without disturbing the pro-poisons, except when able to destroy them, and they will have gained a decided advantage in the struggle for existence. When the bacteria or other producers of alien proteins follow this up by acquiring a rearrangement of their amino-acids that places the pro-poisons in the new place of scission, the advantage the cell secured by its change is lost, and the alien protein is victor. Now let the cell vary once more in the place it selects to split the protein, and once more the bacterium must readapt itself or become extinct. By some such zigzag rhythm of change, giving an advantage first to one side and then to the other, we could have produced protein molecules, the mosaic patterns of the amino-acids of which would differ in all species, but through successive imperceptible degrees. In other words, we would have molecules that in precipitating would shade away from each other as the species shade. They would show the exact kind of precipitive specificity that alien proteins show. We see it to be a fact that their amino-acids do shift their places as race characters shift, do occupy different positions as race characters change, and that the pro-poisons always turn up, as seen by the results of digestion, in the places where they can get their death blows in early. No game of checkers could display more perfectly the moves of skilful play. What wonder that this is so when the stakes are speedy extinction from the earth for failure and a new lease of life for success. This shifting form of the game seems to be perpetual. From the lowest *Protista* to the highest *Metazoa* the same pro-poisons appear to be in use varying in quantities and distribution. Only a small amount of chemical research work has yet been done in this direction, but as far as it goes the evidence indicates that tyrosin, tryptophan, and cystin are present in the proteins of all sorts of organisms. We learn from Abderhalden that tyrosin is "the mother substance of the phenols,"[65] so that when an overworked cell tries to destroy the tyrosin by digestion there is suddenly let loose upon its protoplasm a dose of undiluted carbolic acid or of paracresol. In its deaminization, as well as in the deaminization of all amino-acids, anhydrous ammonia is freed in the same way. The lecithin of the semi-permeable membrane of the cell has a solvent effect on this ammonia and there is a tendency to produce a cytolytic soap through such solution. The presence of lipase will cause hydrolyzation of the lecithin in the presence of the ammonia, thus injuring or destroying the membrane. Such a weakening of the cell-wall would affect respiration and so cripple the defenses of the cell in the presence of a reducing agent. Accustomed as we are to the high degree of resistance displayed by our skins and mucous membranes toward chemical agents, it is difficult for us to imagine the fearful toxicity of the toxins as being due to minute amounts of reducing substances in the toxins and in ordinary proteins. Jacques Loeb tells us that "recent experiments by Castle and Elvolve have shown that substances which have a high reducing power are especially toxic,"[66] and they suspect that this is the secret of toxin poisonousness. That exceedingly minute amounts of protein do kill under anaphylactic conditions is an established fact. That these under or-

dinary conditions are perfectly harmless is known to everybody. It is not, therefore, necessary to here prove the deadliness, but to show the probable characteristic in the food to which the destructiveness that actually occurs is responsible. The amino-acids, as such, are evidently all quite harmless. Rosenau and Anderson showed that tyrosin could not produce anaphylaxis.[67] There is an immense difference between a suddenly released chemically active radical in the midst of the cell's protoplasm and an inactive crystalline mass of molecules of the same substance in the circulation. This every chemist is fully aware of. The difference is of a kind with the difference between grasping a bar of iron when red hot and grasping the same iron when cold. But it is probably not the pro-poison amino-acid radical that is the chief source of the mischief, but its still more active smaller chemical fragments. This is very evident in the case of cystin, the chief sulphur carrier of our bodies. Nothing could be more harmless than a mass of cystin, but imagine its being broken up by our cells in close proximity to the nucleus, particularly under the conditions which anaphylaxis most likely produces. Exhausted by the overtask of disposing of more alien protein than it is in the habit of having to deal with, injured in its semi-permeable membrane by the ammonia so that its supply of oxygen is seriously impaired, struggling in an effort of trying to oxidize the unusual mass of unusable material that can only be gotten rid of in that way, and with less than sufficient oxygen for normal conditions, where does it find itself if suddenly compelled to meet a freshly released quantity of nascent, electrolytic sulphur from broken up cystin? The food current flow is from the membrane to the nucleus, so that normally that sulphur could not be expected to escape reaching the same.[68]. In the absence of free oxygen what ordinarily would any chemist expect that sulphur in that place to do? Recall the intense reducing power that nascent sulphur possesses. Think of its oxygen-hunger where the only available oxygen is locked up in loose bonds with the phosphorus of the nucleic acid. Think of this nucleic acid being the key to the citadel of cell-life. In nuclein we find the chemical substance of the cell chromosomes now generally identified as the basis of heredity in all forms of living things. Think of this nuclein in nerve-structure as being our holy of holies of the soul, the parting of the ways between the living and the dead. Think of these holding their share of this cystin and seeking to get rid of it. What more natural from a chemical viewpoint than that that sulphur would seize the oxygen of the nucleic acid and convert itself into sulphurous acid. This we can readily imagine would start a reversal of the ordinary processes of life. The sulphurous acid would seize more oxygen and convert itself into sulphuric acid. Let enough of this be formed to produce the slightest possible acidity within the cell and then—goodbye to the life of that cell. Instantly by its own enzymes it would change into a digesting mass to disappear soon within the circulation in solution. It would melt away like snow before the sun. We do not know how much acid would be needed to produce such a result, but that it would most likely result as an effect of autolysis if enough acid was produced is an established fact. That in all serious infections evidences of the beginnings of autolysis are discovered is also an established fact.[69] Is it not a singular coincidence that the very results we anticipate from the facts are the exact results that are found. The nuclei of the phagocytes in such conditions have been found to show signs of great injury. The lobes increase in number, become more prominent, as if inflamed, and finally "break down or are used up in the blood."[70]. Let us add still another to the list of these remarkable coincidences. The earliest manifestation of anaphylactic shock is the rush to the lungs of the leucocytes that get the first dose of the foreign protein. This is a movement of obvious selective value, and it will not astonish anyone who has experienced the effects of breathing the fumes of burning sulphur. The instinctive gasp for breath and rush for a supply of fresh air is not unlike the actions of sufferers from anaphylactic dyspnea. Von Pirquet tells us that in the blood, after anaphylaxis, "a large number of transition-forms and large mononuclear cells at the end of the leucopenia suggest a destruction of leucocytes."[71] Before closing, in order to complete our picture as far as known facts are at present able to guide us, we must remember that under the conditions which have been described the cystin is fortified with released tryptophan. Mann says that tryptophan "has very strong reducing powers, as the chlorides of gold, platinum, and palladium are reduced" by it "in a few seconds."[72] It is certainly not difficult to see what short shrift such a substance would be likely to make in the breaking up of a cell nucleus, after learning that it can rend the salts of the noble metals asunder with apparently as much ease as the same result is obtained by an electric furnace.

THE TREATMENT OF EPILEPSY.*

BY EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK,

INSTRUCTOR IN NEUROLOGY, COLUMBIA UNIVERSITY; CONSULTING NEUROLOGIST LINCOLN HOSPITAL; ATTENDING NEUROLOGIST, NEW YORK CITY HOME FOR AGED; NEUROLOGIST WORKHOUSE AND PENITENTIARY; ASSISTANT VANDERBILT CLINIC.

THE treatment of epilepsy is either surgical or medical. It is surgical, however, only when there is undisputed evidence of the presence in a given part of the brain or skull of a definite or removable source of irritation. If the epilepsy is due to the presence of a new growth, to a depressed piece of bone, or to a fracture the treatment is surgical. If, on the other hand, there is no local disease of the brain, no signs of injury to the skull, and no indications of the presence of tumor or abscess the treatment is medical. Without definite indications simple trephining does little good; the removal of a part of the cortex does harm. As only a small fraction of the cases of epilepsy require surgical measures, and as a very large proportion require medical treatment, I am going to pass over any further consideration of the surgical side of the subject and devote the paper especially to the medical treatment.

*Read before the City Hospital Alumni Association, April 19, 1911.

We have to go back almost five hundred years to find the first reports of the treatment of epilepsy. In 1536 the "Cronikles of Scotland" contain an article written by Hector Boethius, in which he describes castration as a method of cure. Even in those distant and dark ages the Scot was canny. He did not know how to castrate his epileptic women, so he incarcerated them. The followers of Æsculapius believed that venery cured epilepsy. Sinabaldi in 1643 advocated coitus as a cure for severe forms of the disease. Pliny advised the stones taken from the claws of young swallows. Antheus believed that the convulsions should be relieved by giving to the patient a dish of human brains. Another one of the ancients, Tralliarius by name, was fertile in resources. He advised the liver of a small weasel freed from bile to be taken three successive days on a fasting stomach. Still a different cure which he suggested was a preparation made from the skull of an ass. Celsus had a remedy different from any of the others. It was the warm blood of a recently slain gladiator. Speaking of it he said: "The atrocity of the disease renders more supportable the atrocity of the remedy." It is said that Abraham Boerhaave, a nephew of the celebrated Boerhaave, used it with much success in the poorhouse at Haarlem in Holland.

In the medical treatment of epilepsy are two important factors: One is the etiology, the other the epileptic habit. Every effort should be made to discover, if possible, the cause of the attacks and to differentiate the organic from the toxic and the idiopathic from either. By the epileptic habit I have reference to the tendency which the disease manifests to perpetuate itself. Each attack renders easier the next. The physician, therefore, should so apply, and so direct his treatment as to break up this tendency. The different means which he has at his disposal to treat epilepsy are numerous. The treatment, therefore, has to be considered from several points of view. I shall take it up under three headings: Hygienic, dietetic, and medicinal.

The hygienic treatment is very important; in many instances it outranks the others. It should begin with a complete history and complete physical examination; it should end with a complete régime. There is no malady the treatment of which requires more care, more skill, and more exactness than epilepsy. The physician should study the heredity, the disposition, and the temperament of his patient. He should familiarize himself with all the physical abnormalities; he should correct all the reflex sources of irritation. Eye-strain, nasal polypi, carious teeth, adenoids, a tight prepuce, pelvic disorders, intestinal worms, and flat feet must be looked for and if found promptly corrected. Any one o fthem may, in a constitution as unstable

as is that of the epileptic, serve to accentuate and augment the disorder. The next step should be to obtain control of the patient. To treat an epileptic successfully means to control him. The best way to control him is to treat him by the colony system, a system which gives the best results.

We now come to two entirely different problems—colony treatment and home treatment. The most successful colony in this country is the Craig Colony, at Sonyea, Livingston County, N. Y., where several thousand epileptics live. The Craig Colony is far too small and inadequate for its present demands. It is always full. The patient, who to-day applies for admission will probably become a member only after several months of waiting. There is no greater need in the State of New York than an endowment for a newer and larger colony for epileptics. The rich men of to-day who are seeking methods of distributing their wealth and of benefiting the unfortunate can find a noble, a real, and a lasting use in the founding of an epileptic colony. It is a charity which would not only aid the sick and brighten the lives of hundreds, but be of untold benefit to this and future generations. The ideal colony should be an estate in which the larger part of the inhabitants consist of epileptics, of which those less affected should be trained to care for the others. The estate should be extensive; it should have a farm, a garden, training schools, and cottages. The patients, to a great extent, should aid in producing what they consume. The general plan should be cooperative. In such an establishment employment more or less congenial can be found for every inhabitant. There should be rules, but few restrictions. There should be no walls and no locked doors. Everyone should be taught to respect the rights of every other member. The patients should, not only be allowed but encouraged to go about. Their interests should be fostered; their tastes cultivated; their idiosyncrasies ignored. It should be a busy community, divided into many departments, over each of which a strong hand and a pleasing personality should preside. It is always of great benefit to the epileptic to realize that he is one of a community the members of which in no sense differ from himself.

The colony tract should be large and removed from the noise and tumult of the cities, a place where the epileptic may enjoy an abundance of light and of air, together with a feeling of freedom. The patients should live in detached cottages; in this way the mild and severe cases need not come in contact. There should be schools, where those able to, may learn; there should be trade and manual training schools, work and carpenter shops, etc. Those patients for whom the outdoor life is most needed should be employed in the garden and farm. Amusements of all kinds should be provided—croquet, tennis, golf, games, concerts, and plays. The patients should be kept busy, profitably employed, and agreeably amused. The result of the colony treatment is very satisfactory; the patients love the sense of independence and isolation; they gain assurance and hope. They no longer feel that they belong to a class apart.

There are, however, many epileptics, who must live at home, who must even attend to their regular business. These, in order to do well, must be under the constant care of a physician. They must live a regular life. The only way to bring this about is to write out for them a regular plan of life. The epileptic requires a strict régime. It must cover every point in detail. Nothing must be left to chance. The day must be occupied. Plenty of outdoor life with two long walks, a cold shower in the morning, a series of occupations and another series of diversions must all be provided for and specified—each one according to the practical requirements of his own case. The patient should be encouraged to read; if possible, to study. He must do manual work. Gardening, farming, carpentering, keeping chickens, raising dogs, are all occupations which keep the epileptic interested and at the same time afford him fresh air. The man who has to live in town can shorten his hours of application and devote an hour to walking, or in bad weather to a gymnasium. In summer he can live six months in the country, where he can add golfing, croquet, and perhaps tennis, and yet be near enough to town to attend to his business. The hour for retiring and the hour for meals must be rigidly adhered to. The patient must be impressed with the importance of attention to the bowels. The bowels must be regulated; unfailing and incessant attention is here required. An overloaded colon, either from its mechanical position or its possibilities of toxic absorption, will frequently superinduce a series of attacks.

You will notice that in one of the above mentioned four rules of diet it is stated that these patients must eat slowly and rise from table hungry. The reasons for giving this so great prominence and again emphasizing it are twofold. In the first place it is characteristic of the epileptic to display little judgment. He is not a man of any discernment whatsoever, and least of all where his appetite is concerned. He will sit at table and literally devour everything put before him and then clamor for more. In the second place it is equally characteristic of these patients to eat their food rapidly and without masticating. It is by no means an unusual sight to see an epileptic take an entire slice of bread, a large piece of meat or a whole potato at one mouthful. A moment later and he swallows it. The food in this way reaches the stomach unprepared, and may very readily precipitate an attack of indigestion or induce a series of convulsions. A large appetite is symptomatic of the disease, and I believe that abnormal attacks of voracity are often the forerunners of a series of attacks. Another very important rule is that the heaviest meal should be eaten at noon. This avoids the important digestive work being done at night. The digestive tract of the epileptic is peculiarly sensitive; it takes very little to throw it out of gear, and once out it takes a long time to get it back in working order. Eating irregularly and constant nibbling between meals always is disastrous. There is no one factor which is more apt to disturb the unstable equilibrium of these patients than a disordered digestive apparatus. An infringement of the rules for diet can often be pointed to as the exciting cause of a series of attacks. As far as drinking is concerned, there is, of course, no time at which an epileptic can take the liberty of drinking even the smallest amount of alcohol.

The home surroundings of these patients must be made as attractive as possible. They are apt to consider themselves as persons apart; their egotism is very great, and they are constantly on the lookout for slights and petty insults. The result is that not only is it difficult to live with them, but that as a rule family life is detrimental to them. The least untoward circumstance, the slightest source of

irritation, may at any time disturb this very unstable and poorly balanced temperament so as to bring about a series of attacks. Another important point in the home treatment of these patients is that every effort must be made to avoid having their life appear too unusual or different. It is always detrimental to the epileptic to feel that he lives a life apart. Persistency in the régime, persistency in the hygiene, and persistency in the diet are factors essential to a successful outcome. It is always difficult for these patients to realize that because they are a little better they cannot take liberties. The epileptic is apt to go to extremes, so that when he has begun to improve he is just as much, if not more, in need of medical advice than when he is not doing well. It is the constant and close observance of a strict régime that will favor his recovery.

The second part of the treatment is the diet. Here two objects are in view: First, to eat nothing that will disturb an unstable equilibrium; and, secondly, to modify the diet so far as possible in order to permit the minimum dose of bromide. The way to attain the first object is to give the patient food in which the purin bodies are absent or nearly so, and at the same time a diet in which there is no indigestible matter left in the intestinal tract to serve as a source of irritation. The way to attain the second object is to restrict the consumption of salt. It should be kept in mind, however, that no two cases are alike and that exceptions will have to be made. A weak and anemic patient will require meat, and should have it; a hard-working epileptic will need it. The following four rules should be enforced in regard to the diet. (1) He should eat slowly and rise from table hungry. (2) The heaviest meal should be at noon, the lightest at night, and under no circumstances should he eat between meals. (3) He must not eat anything fried, no indigestible dishes, no liver, sweetbread, hot breads, veal, pork, candy, cake, pastry, and no fruits or vegetables containing indigestible seeds. (4) He must drink only milk or water.

It would seem that this plan would greatly restrict the diet and afford the patient meals neither suitable nor palatable. These two objections can be overcome. The epileptic can be taught to live comfortably on cereals, milk, fish, eggs, butter, bread, and potatoes. He can still eat many of the vegetables and fruits. He must not have vegetables and fruits containing seeds; on the other hand, tomatoes can be passed through a collender and string beans can be mashed. He may not have berries, but there are oranges and peaches, pears, and ripe apples. There are all the stewed fruits. He may not have the coarse fiber of celery or cabbage, but there are lettuce, spinach, and squash. He may have a ripe melon or grapes from which the seeds and skin have been removed. He may not eat corn on the cob with its indigestible envelope, but this can be prepared in a pudding. He may not have the raw banana abounding in granules of starch, but this by baking can be made both digestible and palatable. The absence of salt seems at first an insurmountable obstacle. This, too, can be overcome. It is surprising how many patients can easily adapt themselves to a very marked reduction of salt. Again an intelligent housewife can take the salt away, and in its place substitute cinnamon or vanilla, so as to leave the dish by no means uninviting. Condiments are better omitted, but a simple spice or the addition of a vanilla bean is far better than too much salt. Still another way to help the patient is to let him take the bromide as a salt. The exact dose can be measured, placed in a salt shaker, and can then be shaken over his vegetables. Meat he may have. Many need it. It must be well cooked, never fried, and slowly masticated.

The third part of the treatment is the medical. This consists of (1) the treatment during attacks, (2) the treatment between attacks, and (3) the treatment of status epilepticus. The treatment during an attack is simple. Prevention and expectancy describe it. Prevent the patient from injuring himself and await the completion of the fit. Something soft, preferably a piece of india rubber, should be placed between the teeth to prevent an injury to the tongue. There is always danger from suffocation if the attack occurs at night, and from drowning if it occurs in the bath. This latter may seem improbable, but it so happens that I lost a patient while she was bathing. She was alone, had an attack, and was drowned. When the attack is over the patient should be placed upon a sofa or a bed and allowed to sleep. The prevention of an immediate attack is at times possible but of questionable value. A pearl of nitrite of amyl crushed in a handkerchief, sometimes friction, or a slap on the face may arrest an impending attack. Another way to avert attacks is to apply around the limb in which the convulsive movements originate a tight ligature. This method is very ancient; it was frequently employed by physicians of the sixteenth and seventeenth centuries. The originator of it was Pelops, the master of Galen, who believed that following the aura a vapor ascended the limb to the brain.

This brings one to the consideration of the drugs which may be used in the treatment of epilepsy. There is no specific drug for epilepsy. Of all, bromide ranks first, but it is *not* a specific. It does not cure; it does ameliorate. It renders the seizures less frequent and less severe. To attain the best results it must be begun early, continued long, and never stopped abruptly. The use of bromide in epilepsy dates back more than half a century. In one of Gowers' articles occurs this interesting little paragraph: "Bromide of potassium was introduced into the British Pharmacopœia in 1835, but was removed as useless in 1851. Six years later, or, to be exact, in 1857, Sir Charles Locock advocated its use in epilepsy occurring at the menstrual periods. It was four years later, in 1861, that Sir Samuel Wilks testified to its value in ordinary epilepsy. Then, in 1862, Dr. Goddard Rogers published some cases successfully treated by bromide of ammonium, and in 1863 Dr. Ramskill reported a single case treated by bromide of potassium at the Queen Square Hospital. In 1864 Dr. McDonnell advocated its use. Thereafter it became general, so that to Locock and McDonnell should the credit be given." The bromides should never be considered as the cure for the disease, only as an adjuvant. They should never be given with the object of controlling the attacks, only as an *aid* in so doing. They should never be given indiscriminately. It should be borne in mind that a prolonged or excessive use of bromide may give rise to symptoms which are in themselves more detrimental than the disease. A daily dosage of more than sixty grains is excessive and apt to do harm. It is far better for the patient to suffer from epilepsy than bromism.

I have previously said that the most efficacious way to restrict the consumption of bromide is to

restrict the consumption of salt. On the importance of this point all authorities are not united. Many do approve it. It should always be borne in mind that by too great a restriction of salt one may err. Weyse, the German observer, has studied this question at some length. He believes that the symptoms of bromism have been erroneously ascribed to an overdose of bromide, that they are in reality due to chloride hunger. His proof lies in the fact that he has relieved the symptoms of bromism by the administration of the chlorides. To my mind a patient on a salt-free diet should be carefully watched; on the other hand, I do believe that a restriction of salt means a restriction of bromide. One of the secrets of bromide administration is that once having begun the administration of bromide it must never be stopped abruptly. A sudden decrease of bromide means a sudden increase of epilepsy. Bromide should be given over a long period of time—a very long period of time. As the length of time increases the efficacy of the drug increases. The hour of administration is important; the best results come when the drug is given three or four hours before the expected attack. If the seizures are nocturnal the bromide should be given a little before retiring; if the seizures are diurnal the bromide should be given on rising. The question is often asked: which preparation is the best? I should say that each case is a law unto itself. It is best to try the different preparations and then select the one which gives the best all-around results, not necessarily that one which results in the fewest attacks, but the one which attacks the patient in the fewest ways. As a rule the sodium salt is the most effective as it is the least depressant; the strontium is the least effective, but also the least apt to produce an acne. The bromides give better results when used in combination. Two bromides are better than one. The great disadvantages of bromide are the depression (both mental and physical), the loss of memory, and the rash. A marked loss of memory is oftener due to bromide than to epilepsy. The rash can often be held at bay by the free use of hot baths and, as Echeverria suggested in 1870, by the addition of a few drops of arsenic.

There are many other ways of giving the bromides and many different preparations have been devised. Then, too, the bromides may be given in various and sundry combinations, both with each other and in conjunction with other drugs such as digitalis for those cases that have low pressure or weak heart muscle, and with nux vomica for those who have stomachic disturbances, etc. A well-known treatment is a combination of opium and bromide. This is known as the Flechsig treatment; it consists in keeping the patient well under the influence of the opium for some weeks, then suddenly withdrawing it and substituting large doses of bromide. This Flechsig treatment has been recommended by Peterson in old and obstinate cases, where all other means have failed. Codeine has been tried in conjunction with bromide and is in certain cases of value.

Next to bromide the drug which has powers of most value is borax It may be given in twenty-grain doses three times a day, or if used in combination with bromide in larger dosage. To Gowers is due the credit of introducing borax. Another drug which has been tried is nitroglycerine, where there is the added element of contracted arteries or high blood-pressure. Horse nettle was introduced by Napier; the tincture of simulo has been used. Then there is antipyrine, acetanilid, and phenacetin. Their use is laregly empirical. With their administration the tendency to cardiac depression should always be borne in mind. These are all poor substitutes for the bromides. Chloral and chloroform should be mentioned. Their value is more in acute conditions than in the routine of regular treatment. Calcium lactate has been mentioned by an English observer. He has reported several cases as being helped by twenty grains three times a day. Later observers have verified this. Dr. Starr, who is with us to-night, has tried it. He will, I hope, later on tell us how he regards it. The use of belladonna in epilepsy dates from the seventeenth century. It was recommended by Mardorf, in 1891, and later was a favorite remedy of Trousseau. Since the advent of bromide its use has become less general. It is of most avail in cases of petit mal and those complicated with nocturnal incontinence. The best results are obtained where it is given in conjunction with the bromides. The best preparation is the tincture in doses of from five to ten minims. Digitalis is useful. The best results are obtained by combining it with bromide. As far back as 1640 Parkinson advocated its use, as we see from reading this extract on foxglove from his "Theatre of Plants": It hath beene of later experience found also to be effectuall against the Falling-sickness, that divers have been cured thereby; for after the taking of the decoction of two handfulls thereof, with foure ounces of Pollipody, of the oakbruised made in Ale, that they have been troubled with that disease 26 yeares, and have fallen once in a weeke or two or three times in a moneth, have not fallen once in 14 or 15 moneths, that is until the writing hereof, which I think may be said to be an absolute cure, not to be presumed that after so long stay it should returne againe."

Let me sum up the drug question for you and try to put the conclusion in a few wrds.

Bromide is the drug *par excellence* for use in epilepsy. It should be tried in different combinations and with different preparations. If, after repeated trials, it is found that none of the preparations prove effective, the physician should then go through the list of available remedies, trying each in turn. Resort to opium should not be had unless all else fails. As to the use of drugs other than those I have mentioned, the physician should be as free and ready to use them as in any other condition. The epileptic often suffers from anemia and then should have iron; he often suffers from irregular and intermittent cardiac action and then should have digitalis or strophanthin; he often suffers from lowered resistance and a general run-down condition and then should have strychnine.

Status.—Status is a temporary state, which occurs in the course of the disease. It has been called the climax of epilepsy. A satisfactory definition is difficult. It is a condition in which the attacks occur wth so great frequency that there is no return to consciousness between them, but coma and exhaustion are continuous. The treatment of status involves the treatment of threatened status, or status itself, and of the stuporous stage. The treatment of threatened status is simply the treatment of an exaggerated and accentuated epilepsy. When it is seen that the attacks are becoming more and more frequent and increasingly violent it is then time to realize that danger is impending and that status threatens. There is but one course to pursue,

and that is to increase the bromides, hoping in this way to avert the threatened catastrophe. Chloral and opium may be added and the whole given by rectum. If, however, the increased administration of the bromides fails to bring the necessary reduction and the attacks increase, the convulsive stage has been reached. It is then that the threatened condition has merged into the real. The patient in the convulsive stage requires heroic treatment. The attacks now follow each other without intermission; the last convulsion, with its attendant exhaustion, has not passed before the next announces itself. In this stage the physician must rely entirely upon rectal medication. His sheet anchor now is chloral. It may be augmented with opium or bromide. Thirty grains of chloral with a dram of morphine solution (U. S. P.) is a safe dose. Chloroform may be resorted to as a more immediate remedy. From then on the treatment should be guided by the condition of the temperature, pulse, and respiration. As there is generally difficulty in swallowing it is best to stop the administration of nourishment. The condition of the heart must now be closely watched and the tendency to overdosage guarded against. The condition rapidly merges into the stage of coma and exhaustion. Here the treatment should be supportive and directed to the maintenance of the heart action. The patient is exhausted, vitality is lowered, and every possible means should be resorted to: strychnia, digitalis, whiskey, and the injection of salt solution. Oxygen and faradization of the phrenic nerve may be resorted to.

In the treatment of epilepsy cures are rare, but many practitioners can cite examples. I think it is best to start out with the idea not of curing but of relieving and of reducing the number and severity of the attacks. The idea that I have hoped to convey is that the treatment of epilepsy is a problem of no mean size. He who undertakes to care for an epileptic must realize that he has a problem which will require all the skill, all the tact, all the perseverance, and all the knowledge which he can possibly acquire. He must be prepared for relapses and disappointments. In almost every case, however, he will be rewarded by seeing a considerable improvement. The criticism will no doubt be made that I have outlined a treatment suitable only for the man of independent means and not for the worker, the city dweller, or the submerged element. This criticism at first sight may appear true. A close inspection, however, will show that the treatment of epilepsy can be modified to conform to all but the most ignorant. The lowest order should not attempt to stay at home. For them the competition and the stress of life are too great. Their place is in the colony. The man of moderate means can follow his calling in a smaller town, the man with no especial equipment can keep a country store or do gardening. In this way he can have the benefits of the outdoor life, the exercise, and the careful régime.

In conclusion it may be stated that it is neither the quantity nor the quality of the bromide that is going to help the patient. It really matters very little whether one gives him the warm blood of the gladiator or the warm blood of the ox. The main object should be to find the cause of the epilepsy and remove that. If on the other hand no cause exists, if there is no new growth, no depressed fracture, which surgery can reach, if there is no toxic factor which a temperate life can remedy, if there is no organic disease which medicine can alleviate, then the treatment must be one founded on common sense. The aids which one will then have to call in will be hygiene, diet, and lastly drugs.

54 West Fiftieth Street.

FACT AND FANCY ABOUT THE HOOKWORM.*

By HENRY J. NICHOLS,

CAPTAIN, MEDICAL CORPS, U. S. ARMY.

The modern "world movement," recently so brilliantly outlined by our distinguished ex-President, is particularly noticeable in medicine. As physicians we are interested not only in our own specialties or in local medical conditions, but we have some real curiosity and knowledge about sleeping sickness in Africa, pneumonic plague in China, and especially about various health movements in our own country and dependencies. The modern physician can say "Nihil morbi est alienum a me" with some real meaning, because never before have we penetrated so far into the subtle processes of disease and never before have we looked out on such a wide horizon in the geographical distribution of disease.

It is because of this cosmopolitan spirit in our profession that I venture to present this evening some features of hookworm infection. The hookworm does not prevail to any appreciable extent in New York State, and from its nature cannot gain much of a foothold here. Imported cases, of course, occur and it is, of course, desirable that such cases be recognized. In 1897 Dr. Mohlau of Buffalo recorded a severe case in an Italian laborer, and Captain Siler, U. S. Army, has recently found 85 per cent. of Southern born recruits more or less infected at Fort Slocum, N. Y. Occasionally, too, these imported cases may give rise to an indigenous infection. Dr. Mohlau mentions two cases of this kind, one in an adult and one in a child, who were probably infected in a brickyard where Italians worked. In 1910 Brooks recorded a case in an American 55 years old, who had never been out of New York and Pennsylvania, and who was probably infected while working in trenches at Brewster, N. Y. This case went through three hospitals with a diagnosis of pernicious anemia; his hemoglobin was 25 per cent., his eosinophiles 21 per cent., and a considerable number of parasites were recovered. But the cases which are infected in this latitude are rare and must necessarily be rare. Hence there is no danger that this infection will become widespread in this or other Northern States.

As Boycott has clearly pointed out, three conditions are necessary for the spread of hookworm disease: (1) a certain degree of temperature about $68° = 90°$, (2) a certain degree of moisture, (3) fecal contamination of the ground; and these conditions are found only in tropical and subtropical regions. When the temperature here is suitable for the hatching out and development of the embryo hookworm, the weather is usually too dry; and while the sanitary arrangements, especially in the country districts of New York State, are probably not ideal, they are not to be classed with those in the Tropics. In one town of 6,000 inhabitants in the Philippines we found that 45 per cent. of the houses had no provision whatever for the disposal of excreta and that only 6 per cent. had an arrange-

*Read before the Academy of Medicine, Syracuse, N. Y., May 2, 1911. Published with permission of the Surgeon-General U. S. Army.

ment which was at all satisfactory. In six Southern States Stiles found that of 1,700 farmhouses occupied by whites 35 per cent. had no privy, and of 1,600 houses occupied by negroes, 80 per cent. had no privy—with an average of 57 per cent. of households whose wastes were necessarily deposited on top of the ground. In England and Northern Europe the disease is found only among mine workers and only in particular mines where the temperature, moisture, and habits of the men are such as to allow the parasite to go through its extracorporeal cycle. In 1903 Dr. Wainwright and I examined the stools of 400 miners from many mines in the heart of the anthracite coal region and found only one case of infection, which was probably an importation.

If, therefore, from the standpoint of actual experience the Northern practitioner must look on the hookworm as more or less of a curiosity, what should be his attitude from the standpoint of scientific and patriotic interest? This question can best be answered by reviewing our own ample experience, as a country, with hookworm infection.

In the year following the Spanish War a devastating hurricane visited Porto Rico, and Captain Bailey K. Ashford of the Army Medical Corps was directed to establish a field hospital at Ponce to care for the victims who could not be accommodated in the hospitals of the city. Captain Ashford says. "Fully three-fourths of those admitted were suffering from anemia, which was usually attributed to faulty diet. Later, as generous food with iron and arsenic failed to cure, the condition was attributed to malaria, climate, lack of hygiene, etc., all of which proved upon investigation to be inadequate causes." Some physicians declared the condition to be pernicious anemia and, with this idea in mind, Ashford examined the blood. He was struck with the high percentage of eosinophiles and, remembering the association of trichinosis and eosinophilia, he began to examine the feces for parasites and immediately found eggs which he identified as those of the hookworm. This was a fairly simple procedure, but it meant much for the 600,000 rural inhabitants of Porto Rico. As a result of the subsequent work of Ashford and his associates, it was shown that 90 per cent. of the rural population was infected with hookworm and that at least 50 per cent. were damaged by the infection, having a hemoglobin content of 50 per cent. or less. Out of 4,500 cases of anemia only 6 were due to other causes than the hookworm. The number of parasites in these cases ran into the hundreds and thousands. Thirty per cent. of all deaths were due to the hookworm. But since these facts were established 300,000 persons have been treated, a great majority of them successfully, and the yearly death rate has fallen by 5 per 1,000. It may be accepted as solid fact that hookworm disease is a serious matter in Porto Rico and that much may be expected from treatment and measures to prevent infection in that island.

As a contrast let us look at the situation in the Philippines. It was, of course, a natural result of the success of the hookworm campaign in Porto Rico that health officers should take up the question of a similar campaign in the Philippines. Thus the Director of Health stated in his report for 1908: "This office is convinced that the proverbial reputation for indolence gained by natives of tropical countries is due, in a large measure, to hookworm disease," and again, "it is against this condition that special efforts are to be directed and from which the greatest measure of success is to be expected."

Is this fact or fancy? In 1909 a party of which I was a member made a medical survey of a Filipino town of 6,000 inhabitants. Among other examinations were those of 1,000 persons of all ages for hookworm ova. Only 11.6 per cent. were found to harbor the parasite, and among those infected we were unable to find a single instance of anemia or to observe that they had more of the proverbial laziness than those noninfected. Dr. Garrison of the Navy, who was in charge of this work, summarized it by saying: "The absence of clinical manifestations, the small number of worms found in infected cases, and the low percentage infected indicate that the hookworm plays a very small part in the sanitary conditions encountered in this typical Filipino town." Dr. Rissler has since then reported the results of nearly 10,000 examinations in three other parts of the islands. In one place he found 11 per cent., in another 8 per cent., and in a third 45 per cent. infected. He says: "Cases exhibiting typical symptoms of uncinariasis are rare. A few persons have complained of discomfort in the abdominal region, which has been relieved entirely by treatment which resulted in the expulsion of hookworms. Several cases in the Santa Isabel hacienda were picked out by the manager as being typically lazy, but upon examination they were not found to harbor the parasite. The absence of clinical symptoms was probably due to the paucity of the infecting worms. In most cases only five or ten were expelled after treatment, in others only two or three." Everyone who has had actual experience with cases in the Philippines has come to the same conclusion, namely, that, while a number of persons carry the parasite, genuine cases of hookworm disease are not numerous. I have seen several such cases both in white soldiers and in natives with parasite counts in the neighborhood of 100, but in the majority of persons examined, whether clinically or at autopsy, the count has been nearer 10. The facts of the case are that cholera, malaria, dysentery, beriberi, tuberculosis, leprosy, and smallpox are much more important diseases in the Philippines than hookworm disease and that much more is to be expected from measures against them than from measures against the hookworm, as, indeed, has since been stated by the Director of Health.

What is the reason for such a difference in regard to the same infection between Porto Rico and the Philippines? It is largely a question of degree; a question of the number of parasites. As Ashford says: "The essential feature is the number of worms contained in an individual more than all other modifying factors put together." If a person harbors 5 or 10 hookworms, by a careful search ova can be found and the person can be said to be infected, but he will not suffer from anemia or any other symptoms. As Manson says: "there may be dozens of ankylostomes in the intestine without appreciable anemia, or, indeed, symptoms of any description whatever." On the other hand, if an individual harbors many parasites, such as fifty, a hundred, or more, anemia and its sequelæ will develop. Boycott has well emphasized this point by calling his recent lectures "ankylostome infection" rather than "ankylostome disease." It is not neces-

sary for our purpose to go further into an explanation of the difference in degree of infection between Porto Rico and the Philippines except to emphasize the fact that heavy infections are usually the result of repeated infections. In this connection it should be remembered that for each adult worm in the intestine a separate embryo must enter the body usually through the skin.The hookworm is not like the malaria plasmodium and the ameba, which multiply tremendously after introduction. This is an elementary fact, but it is lost sight of at times, as by a physician in charge of some of the hookworm work in the Philippines who thought that, even if a person had only a few parasites at a given time, he might, in a few months, have many hundreds. This is impossible. Constant reinfection, therefore, through exposure of the feet or hands to contaminated ground is most favorable to heavy infection and real damage.

What, now, is the condition in our Southern States? Stiles has been foremost in urging the importance of hookworm infection in the South and he has shown that the negro is probably the reservoir of the parasite and the chief contaminator of the soil. The most prevalent parasite is *Necator americanus,* which the negro probably brought over from Africa in the slave days, as it has been found among the natives in several parts of Africa. Is the condition in our Southern States like that in Porto Rico or like that in the Philippines or intermediate between the two? The boards of health of the Southern States, in conjunction with the Rockefeller Commission, have begun to make systematic examinations, and from their work it is becoming evident that the condition is an intermediate one. In certain parts of North and South Carolina, Georgia, Alabama, and Mississippi, along the coast, the general infection has been found to be high, 40-80 per cent., approximating the condition in Porto Rico. In this area a good deal of real damage must and does occur and much may be expected from treatment and from prophylactic measures. In other areas of the same States, toward the mountains, the infection is low, under 20 per cent., a condition more like that in the Philippines, and in this area it may reasonably be expected that the hookworm is of much less importance than several other disease-producing parasites. To have much real hookworm disease it is necessary that the general level of infection should be high. For example, at the Dolcoath mine in Wales, Boycott found 95 per cent. infected and only 5 per cent. sick; in the Grenville mines 12½ per cent. of 800 men were infected and none were sick. As I have tried to show the essential point is the degree of infection, which is or should be a familiar conception in medicine. All of us at one time or another have an occasional organism in our blood streams, but we are not on this account put down as suffering from septicemia. In the surgically clean wound which heals by first intention a certain number of organisms can be found by section of the scar, but we do not call this abscess formation.

This distinction between hookworm infection and hookworm disease may be difficult for the lay mind to grasp, but there is no reason why it should not be thoroughly understood by the profession because it is of fundamental importance, clinically. From the standpoint of spread of the disease light infections must be reckoned with, but from the standpoint of a diagnosis and treatment of a given patient, light infections are practically negligible. It is needless to say that this distinction has been entirely lost sight of by the laity and by many physicians in regard to the condition in the Southern States. All cases of infection have been lumped together and all sorts of peculiar symptoms have been attributed to this parasite. It has even been asserted that the only trouble with the "poor white trash" is that they have hookworms. In short, there is plenty of evidence that enthusiasm for something new has in many instances outrun scientific candor and sound clinical conclusions. The chief reason is that the agitation about the hookworm has been based largely on the mere finding of ova in the feces without regard to any correlation between the presence of parasite and any tangible evidence of disease. Thus, whole schools, teachers and all, have been reported as infected without any information as to whether these persons incidentally carried a few negligible parasites in their intestines or whether the parasites had been or were, at the time, present in sufficient numbers to cause damage. We have seen something of light infections from the South in the Army. Many recruits carry a certain number of worms, but as is stated in the Surgeon-General's report the height and weight of these men is above that of all recruits taken together, and clinical symptoms referable to the hookworm are rare. It would be ungracious and unfair to try to minimize the efforts of those who are working against the hookworm where it is doing real damage. But it is equally poor clinical medicine, poor ethics and poor policy to ascribe to the hookworm damage which either does not exist or is due to other causes. There are plenty of real ailments against which to work without wasting time on windmills and I am convinced that in many parts of the South, malaria, typhoid fever, and dysentery are doing more real damage than the hookworm and that the most important result of efforts against the hookworm, along the line of the proper disposal of excreta, will be the indirect effect on the reduction of typhoid fever and dysentery, and that the general stimulus toward cleaning up things may have the same effect in regard to malaria.

In his letter of invitation Dr, Steensland mentioned a desire to have a paper especially on the clinical aspect of hookworm disease and this has been rather a roundabout way to arrive at this aspect, but I felt that I could not do better than give this view of hookworm infection as a background for proper clinical work, because these general views have a direct application in a given case. For example, not long ago we were consulted by an officer who had been in the Philippines and Africa under field conditions. He was suffering from insomnia and thought he might have hookworms. Examination of the blood was negative, while examination of his stool showed a few hookworm eggs, and after a course of thymol eight worms were obtained. No more eggs were found and the symptoms did not abate. As a matter of fact, we knew from other examinations that we were dealing with diabetes and pursued the hookworms simply to satisfy the patient. If a patient is anemic or has palpitation, dizziness, and shortness of breath and edema, the proper rule of clinical medicine is a thorough physical examination and a blood examination as well as an examination of the stool. If the heart is sound, if no malarial organisms are

found, and if an eosinophilia is found, the stools can be examined with intelligence, and if eggs are found in abundance or the use of thymol results in the expulsion of an appreciable number of worms it may be safe to diagnose hookworm disease. On the other hand I have seen an eosinophilia over 30 per cent. as a result of a severe skin infection with fungi, while the stool was clear of all parasites. Other intestinal parasites, too, cause eosinophilia.

In regard to the many bizarre symptoms that have been ascribed to the hookworm, a remark by Dr. Byrd, Assistant Health Officer of Florida, is apropos. "The safest rule to follow is: In all cases of anemia that cannot be otherwise satisfactorily accountd for, examine for hookworms. Don't be thrown off guard looking for dryness of hair and skin which may be as moist as your own; protrusion of the abdomen which may be straight as a bean pole; history of ground itch which you may or may not get; or any other of the hundred and one symptoms with which the literature is teaming, but examine the stool at once for eggs and settle the question." And it may be added, after eggs are found, be sure from blood examination, count of parasites, or improvement of symptoms after treatment that the real trouble is the hookworm before closing the case.

RECENT REPAIR OF THE CERVIX.

By GRANT GOULD SPEER, M.D.,
LOS ANGELES, CAL.

So much has been and is still being written about the recent repair of the perineum that it brings out in sharp contrast the paucity of literature on the closely related operation, the recent repair of the lacerated cervix. Such complete papers as have been written, though based upon successful personal experience, in some cases citing a definite number of operations and their results, have not established this practice as one in obstetrical routine. In view of the long list of sequelæ following the neglect of this most common accident, we feel there must be and is a remedy to be invoked without waiting months or years before the injury is repaired; and that these papers, few as they are, have not had the effect they should have had in causing attention to be given the cervix immediately after childbirth.

The following statistics are not claimed to be complete, as in the last year a new interest appears to have been aroused in this work, and probably there is much to be gathered and much to be reported.

De Neen[1], quoting from Mundé, says that of 2,500 women giving birth to one or more children, 25 per cent. had well marked laceration of cervix, and 50 per cent. of these needed treatment: from Goodell, one in six suffering from uterine disease had ununited laceration of the cervix; and from Ashton, 50 per cent. of lacerations heal spontaneously.

Edward S. Gushee[2], reports for the Lying-in-Hospital, New York City, 1909, in 1,000 cases, 807 lacerated, or 80.7 per cent.; 154 intact; 39 unobserved. Immediate repair, 11, or 1.123 per cent., in all except one for profuse hemorrhage. Two died from hemorrhage.

Stricker Coles[3], Jefferson Maternity Hospital, 1906, reports 2,200 confinements; immediate repair was made in 181, or 1 in 12. All recovered. In 2 cases there was nonunion; in 20 cases, union was fair; in 159, union was good.

Edward McGuire[4] in 1905 reported 28 cases; 23, union good. In two cases infection occurred. All the patients were operated on at home.

I have a record of 22 cases, of which three were septic; one of these began labor with chills and fever; one had a rise of temperature one hour after delivery, and one had fever, due to exposures incident to delivery and after care. All three were curretted with the stitches in situ. In two the results were good; the third had had a recent syphilis and suffered two subsequent miscarriages requiring curettage. Suffering from pelvic trouble, she applied to another physician, who performed a more or less extensive operative repair. Three of the operations were partial failures. The first is narrated above. The second appeared to heal well, but in about two years presented a keloid growth where a small tear had apparently been neglected; this was removed by a simple V-incision. The third was an extensive unilateral tear through the whole of the cervix into the wall of the vagina. This healed through the greater part of its length, but left considerable scar at the external os, followed by subinvolution of the uterus, which will probably require a future trachelorrhaphy. Of deaths there were none. At least five of the women have since given birth to as many healthy children.

By recent repair of the cervix we mean a repair in the puerperium; that is, a repair instituted at any time after the expulsion of the placenta up to the fifteenth day. The reasons for a repair at this time are immediate and remote. The most obvious of the immediate reasons are, in the order of importance: hemorrhage, sepsis, subinvolution, and after-pains. The most prolific cause of post-partum hemorrhage is a gross tear of the cervix. The writer holds this to be true so firmly that he doubts the existence of the so-called atony of the uterus, in which, fully emptied and untorn, the organ refuses to contract. If existence of atony be granted it must be in uterii rapidly emptied by force, in premature labors, and in patients of hemophiliac tendencies.

The most obvious cause of hemorrhage following laceration is the involvement of the cervical portion of the uterine artery, which no doubt is of rather unusual occurrence. The next that attracts our attention is the tearing through the muscular fibres of the cervix. These in the gravid uterus run transversely, interlacing before and behind; and as most lacerations are lateral, rarely ever anterior or posterior, it will be seen that these muscular fibres are torn through at what may be termed the belly of the muscle. These two lateral muscular walls, reinforced at the inner and outer os, form the

point toward which all the contracting forces of the uterus are directed. As the fibres of the uterus contract from above downward, the motion ends in the cervix, where the contraction is sustained by the intrinsic nerve-supply that controls the sphincter action of the internal and external os. But if one or both are torn through there is nothing to sustain the completed contraction of the uterus; it is rendered futile and the wave of contraction again takes place, or the uterus remains uncontracted—the so-called partial or complete atony. The paralyzing effect upon the intrinsic nerves of the cervix might here demand our attention were it not that in all labors the cervix receives great punishment followed by no paralysis and no atony. In hemorrhage only such lacerations are taken into consideration as destroy the muscular fibres of the cervix. But in view of infection, it is apparent that each individual crack may be the focus for the reception of septic material, the importance of these smaller injuries increasing with their number and extent. The futility of repairing the smaller ones is apparent, the dressing of which is left to the secretions applied by nature, and only those demand attention that by their size leave large uncovered surfaces. Subinvolution may occur from other causes than the one under discussion; but it is apparent that a laceration of any size in the cervix may interfere with the lymphatic, blood, and nerve-supply, and thus retard the absorption of the redundant uterine tissue. This includes for consideration the congestion and resulting edema that follow any injury, and especially that of a mucus-covered organ like the uterus. After-pains do not seem to be well understood, but are generally ascribed to the retention of blood or secretions in the body of the uterus. These pains seem to occur more often in the multipara than in the primipara. It might then be logically inferred that the inability of the uterus to keep its cavity clear of debris by properly contracting, if this be the cause of after-pains, is due to previous injuries to the cervix.

The remote effects of a laceration at childbirth are too many and too well recognized to be mentioned specifically at this time, but, briefly stated, are those which may be corrected by a well-directed trachelorrhaphy that reduces an hypertrophied, everted, and eroded cervix, presenting masses of scar tissue. to its normal size and shape.

In lacerations of the cervix we may have hemorrhage, the inclination of the empty uterus to dilate, and we have assumed the after-pains; but in many cases there may be no symptoms to be discovered short of a physical examination, the simplest of which is by means of the aseptic finger. When the placenta is expelled, the uterus may be induced by proper stimulation to contract. At this time the cervix forms a well marked ring or fold around the now large os, around which the finger may be swept to find if this ring has a well rounded border and is perfect on all sides. If the finger slips through this fold or encounters a softened or roughened spot it may be considered that a laceration has occurred. But a digital examination is not always sufficient to discover a laceration. It is often necessary to expose the cervix with a speculum, wipe away the secretions, and after drawing one part after another from out of the folds of the vagina, carefully inspect the whole circumference of the cervix. It has been laid down that laceration of one-half inch or more should be repaired, but a better rule is to repair even lesser ones if they involve the tissue sufficiently to threaten the formation of scar tissue, *e. g.*, when the tear is ragged or through the circular fibres on the edge of the os.

Many of these lacerations would recover without assistance; the lochia bathes them in an emollient dressing and the clinging walls of the vagina holds the severed parts together. So will many rents of the perineum recover if kept clean and the patient quiet. But in this day of exact surgery we do not think kindly of one who does not attend to the perineum, and why should we excuse one who neglects the cervix?

The recent repair of the cervix may be immediate or postponed. The immediate is performed as a continuation of the delivery following the expulsion of the placenta; the postponed may take place as late as the fifteenth day. There are minor objections to both of these periods as being the extreme. If done in all cases immediately, the patient and attendant are both weary; there is rather an excess of blood; the parts are all relaxed, and it is often night, when the light is bad. If left alone until the fifteenth day the processes of healing have begun, the granulations have to be cut away, and the operation takes on the character of the secondary trachelorrhaphy, though not so difficult on patient or operator. Done at this late day it keeps the patient in bed long after she might be up and about, and deprives her of the early benefit such an operation insures to the involuting uterus.

The writer's first cases, about six years ago, were all done by election immediately after expulsion of the placenta. The results generally were good in that they were nearly perfect; but there is apt to be a fault at the edge of the os. By this is meant that healing was good until the inner end of the incision, which showed a little notch caused, perhaps, by a turning in of the soft mucous membrane, thus preventing healing at that point.

Further experience seems to point to a compromise between the postponed operation, of the fifteenth day, and the immediate, directly following the expulsion of the placenta. A colleague of mine, who is doing this operation frequently, but whose statistics are not at hand, is very successful in selecting the seventh day, when he does the operation without an anesthetic. The writer prefers a much shorter time to elapse, say, within 24 to 36 hours, after the patient has rested and suitable light and preparations can be obtained.

The technique is very simple. The patient is placed in a lithotomy position, a Sims speculum is introduced and drawn down until the cervix is exposed, and the edge of the cervix on either side of laceration is grasped by mouse-toothed hemostatic forceps or small tenacula. If the tear is recent and straight the forceps, one on each side, are brought down exactly together and directly opposite one another, which will bring the edges of the tear in exact apposition. A rather large, full curved cervix needle, carrying a silkworm-gut ligature, is carried well up the tear towards the vaginal fornix and passed through all coats of the uterus on one side of the tear and back through the other; the two ends of the ligature are held temporarily in a hemostat; another is placed below this in the same manner and so continued until the last one is placed exactly through the two corners grasped by the tenacula. Two to four ligatures are usually sufficient. After all are in place, the upper one is tied first, then the others in the order of their insertion, great care being taken that there is no infolding of the mucous membrane anywhere along the line of suture, and that the corners of the tear come exactly

together to prevent a fault or notch occurring here through not healing. The ligatures are now all brought into a bundle and tied together, and the ends are cut off about an inch and a half from the uterus. Each laceration found is repaired in the same manner. The uterus is allowed to recede, care being taken that it assumes a normal position high up in the pelvis. No dressing is applied except the vulva pad. The patient is allowed to continue her lying-in period, and if the operation is performed early she is allowed to get up on the tenth or twelfth day, as though no repair had been attempted. The sutures are allowed to remain one month, and are then removed at home or at office, as is found most convenient.

In case the tear is ragged, or the torn surface has a glazed or granular condition, as in the postponed operation, the opposed surfaces to be united must be carefully trimmed or freshened with the scissors. The tissues at this time are very soft and this is easily accomplished. In fact, old lacerations may be repaired at this time. The writer has attempted this but once, and that with perfect success. A multipara, fourth child, showed a marked tendency to heavy hemorrhage as soon as the placenta had been delivered. An examination next morning showed a very small tear, but situated at the bottom of an old unilateral tear of the right side, which carried it close up to the circulatory artery and had invaded some of the larger branches. On the fourth day both sides of the old tear were freshened from the edge of the cervix down to the new wound, and the parts were brought together with silkworm gut, as described. Four weeks later the sutures were removed and revealed an os that, aside from a fine linear scar and stitch marks, was nullipara in appearance. The contraindications to this operation are in those cases in which the cervix has received severe punishment and there has been a great loss of tissue that prevents the apposition of the parts, or in which the vitality of the tissue has been so lowered that necrosis is threatened.

The most important objections raised against this operation are the danger of sepsis and the possible loosening of the stitches through involution of the uterus. Hirst[5] has pointed out that there is little danger of infection after the fifth day. In my 22 cases all the operations were done at home and two, at least, of the three infections occurred in spite of, and were not the result of, the operation. In none of the cases where the stitches were properly placed was there any loosening. The involution and contraction of the cervix appeared to take place symmetrically and the stitches when taken out appeared very much the same as in a secondary operation performed a year or more after delivery. In no case was there absolutely nonunion, and even in those cases in which the results were not perfect, there was less eversion of the cervix and thickness of scar tissue than one would expect from the extent of the injury if left to nature. Taken in all their aspects, the results of this operation have been most gratifying to the patient and operator. When one is familiar with technique the end-results should show a less number of failures than in repair of the perineum under the same conditions.

SOME PERSONAL REMINISCENCES OF LORD LISTER.*

By L. L. HILL, M.D., LL.D.,

MONTGOMERY, ALA.

An ever increasing admiration for my venerated master caused me several years ago to write some personal reminiscences of Lord Lister, which I have been told would be of interest to this association, and thinking perhaps, to use the eloquent language of Edmund Owen, some stray thought may be set free—as when a flint strikes steel—which falling upon the mental tinder of some younger man may cause the springing up in him of a flame to illuminate his studious path and help him onward. Having finished my studies in New York and Philadelphia, I had a great desire to visit London and see Mr. Lister, with whose work I was familiar and whose great name was then claimed by England, but has since become a common heritage. On the first day of September, 1883, I boarded a ship at New York for Liverpool. The day was bright, the air balmy, and the ocean spread out before us like a quiet greenish mirror, bounded to the eye only by a constantly receding horizon. For the first few days the ocean seemed to be the home of halcyon tranquillity—"a sabbath of repose." The very winds seemed quietly to give the waves a kiss of peace, and, with a playful finger, to toy with the locks of the voyagers, and then, with a friendly hand, to press upon the canvas of the ship, as if to aid the struggling steam to put her quickly and safely into port. On the morning of the fourth day out our ship began to rock uncomfortably. Æolus had struck his trident upon a small cave of the winds and a brisk breeze had started. Mercury was falling rapidly; orders were given to furl the sails and lash them securely to the yardarms. Clouds were gathering and forming like men-of-war in battle array; the zigzag lightning ran from one to another, as if they were fiery chains to bind them together in solid phalanx; a lurid hue lit up the sky as if a volcano struggled within its bosom, and the very ocean trembled and the air quivered under the rumbling thunder. Our noble ship had shrunk into a cork; a sharp narrow wave would lift her amidship and she would seem in danger of breaking in two, and her propeller would vainly beat the air or struggle with the waves, wholly submerged. The billows broke over the ship's deck, carrying away the balustrade and life boats. Often she was clear under the waves, but she would bravely rise again, as if resolved never to go down with her precious living freight. Virgil must have been an old sea dog as well as one of the greatest epic poets, as his description of the storm upon the Trojans was fully realized: "For, now in a trough of the sea, we seemed to be at the bottom of the ocean, and again, upon one of its alpine waves, we seemed entangled with the stars, and day and night commingled for several days." It is said that no evil is so great that it has not some mitigating good mingled with it, as is said in Don Juan:

"Fright cured the qualms
Of all the luckless landsmen's seasick maws."

Byron never wrote truer words, for it is a sovereign remedy. We had three clergymen on board, who did their whole duty, as they saw it, for the safety of the ship. When the ship struggled with

*Read before the Medical Association of the State of Alabama, April 19, 1911.

a power which seemed to lift the ocean from its bottom and wash the stars with its briny spray, they did the loudest praying I ever heard. When the hurricane would catch the ship in its spiral whirl and apparently lift it from the bosom of the ocean, when its propeller and rudder were useless things, and then, as a discarded toy, dashed it back upon the rolling billows, they sandwiched their prayers with the cheerful strain of "Nearer, My God, to Thee." Finally the barometer gave token of an abatement of the storm; the wind gradually subsided; the clouds faded away; the glorious sun uncovered his bright face until "twilight pulled the curtain down and pinned it with a star," and hope revived and made happy every heart, and the ship docked in Liverpool on the fifteenth day.

I proceeded at once to London and matriculated the following morning at King's College, and hastened to the hospital, where Mr. Lister was scheduled to hold a clinic. As I passed up the magnificent stairway and entered the operating room my eyes soon rested upon the bas-relief of Sir William Fergusson. I thought of his thirty-four years of active service in the hospital and of his lamentable death, of Bright's disease, in 1877. I could see the great Scotchman, the most marvelous operator of his time, remove the upper jaw, lithotomize, perform his wonderful plastic work, and divide the levator palati and palatopharyngeus muscles as a preliminary to his successful staphylorrhaphy. This same delicacy of touch enabled him to become a great violinist. Like Billroth, Mikulicz, and Rokitansky, he was a lover of all music, from the hand organ to "Tristan und Isolde"; a worshipper of Wagner, Beethoven, and Liszt, "of every eagle that soars in the heaven of sound. Fergusson was an uninteresting lecturer, not well informed about the works of others, and his ideas of pathology were archaic. On one occasion, while lecturing upon caries and necrosis, a student reminded him that his views differed from those of Niemeyer. Fergusson replied: "Sir, Nehemiah was a gentleman who wrote one of the books in the Old Testament, but I have yet to learn that he had views on caries and necrosis." I thought of Soelberg Wells as having been a teacher in the college, and that it was here that Sir Thomas Watson electrified his class with his lectures upon the practice of medicine. Mr. Lister soon appeared, accompanied by his assistant, Mr. Watson Cheyne, whom he brought from Edinburgh in 1877, when he came as the successor to Sir William Fergusson. In the august presence of this great man, who "had divided the history of surgery into two great eras, before Lister and after Lister"; who made the surgery of the past compare with the surgery of the present like the Indian dugout with the *Deutschland,* or the love warblings of the golden oriole with the symphonies of Mendelssohn's wedding march; I was awed into a feeling of suffocated excitement. He was then in the meridian splendor of a fully developed and glorious manhood. Unlike our American professors, he took a seat. He commenced lecturing upon the aseptic and antiseptic treatment of wounds, the chart and compass of all surgical advancement. It occurred to me that I had never seen so thoughtful a face, a more kindly expression, nor a sweeter smile to mirror a great inward soul. He spoke in a conversational tone, with great fluency, and he had a lucidity of statement unequaled by even Mr. Erichsen. As an operator he was cleanly, bold, courageous, self-possessed, but not given to rashness. He wore no operating overalls and had no rubber gloves, but his work was the signboard upon the great surgical highway that pointed to the asepsis of to-day. He taught us avoidance of irritation by antisepsis, for which he used oil silk protective, and the destruction of the microorganisms with carbolic acid before they reached the wound I saw him refuse to amputate in a compound dislocation of the ankle joint with extensive laceration and in a compound comminuted fracture of the leg. I remembered what Gross had taught me, and I thought of what Syme had said, and yet I saw him save both limbs. I saw him operate for malunited and ununited fractures, wire the patella, excise the wrist for caries, resect the knee-joint, and almost do a Halstead in a mammary carcinoma. His article on amputation in Holmes' "System of Surgery" is a classic, and Lister's method of bloodless operating antedates Esmarch's bandage. I had the honor of being one of the students that cheered him in 1883 when he returned from Windsor Castle with a baronetcy, and I rejoiced when he became a peer in 1897. Lister's pioneer work in practical surgery, which entitled him to everlasting fame, has been completely overshadowed by the enormous benefit to suffering humanity from his revolution in the treatment of wounds.

Joseph Lister was born in England, April 5, 1827. His father and grandfather were wine merchants in London. The father, J. J. Lister, was of an eminently scientific turn of mind. He perfected the compound microscope, and "Lister's law of the aplanatic foci remains the guiding principle as the pillar and source of all the microscopy of the age." The year of the birth of his son, in connection with Hodgkin, he determined the diameter of the red blood corpuscles and their tendency to run into rouleaux. The son, Joseph Lister, was graduated in the literary department of the University College in 1847, and five years afterward qualified in medicine. Saturated with scientific heredity and a student and admirer of the great physiologist, Sharpey, it is not surprising that the spirit of investigation and experimentation was early infused into his mind, and that his first paper, the year of his graduation, was upon the identity of the muscle of the iris and involuntary muscular fiber. Entering the University College Hospital, he became dresser for Sir John Erichsen, whose house surgeon was Sir Henry Thompson. Having served his time, and upon the advice of his former teacher and friend, Sharpey, he went to Edinburgh, "to take six weeks of Syme's clinic," but remained six years, married Mr. Syme's daughter, and laid the foundation of a reputation that will "reach the uttermost shores of time." Lord Lister manifested the greatest admiration for his illustrious father-in-law, and frequently during his lectures quoted Mr. Syme's, and would sometimes exhibit pathological specimen that had been collected by the great surgeon. We learn from Sir Hector Cameron, who was Lister's house surgeon at the Glasgow Royal Infirmary in 1861, that he had seen as many as five cases of amputation of the leg die of pyemia in that institution in one week. This made a profound impression upon Lister, who had just been called to the chair of surgery in the University of Glasgow, at the early age of thirty-four, and he immediately went to work to investigate the cause. He taught "that the cause of suppuration in wounds was the decomposition of blood and serum retained within them, brought about in some way through the influence of the atmosphere." Soon after this Pasteur's work on fermentation and putrefaction ar-

rested his attention, and in 1867 Lord Lister struck his level and laid down the great principle of the modern treatment of wounds, and, were it not for him, "the dust of antique time would lie unswept, and mountainous error be too highly heaped for truth to overpeer." In his address before the British Medical Association he stated that septic properties depended upon minute organisms, and that suppuration might be avoided by using some agent capable of destroying them, and recommended carbolic acid. He called the microorganisms which produce suppuration "dust particles," and believed that air infection was the great source of danger, and his carbolic spray was the outcome. He soon discovered that they were omnipresent, and that the greatest danger was actual contact infection, and recommended cleansing of the surgeon's and assistant's hands, patient's body, instruments, threads, and dressings. He saturated a piece of lint with pure carbolic acid and mopped the wound out, afterward covering it with the same material and holding it in position with pieces of tin. The tin was daily removed and the dressings painted with pure acid. He treated abscesses by mixing pure carbolic acid with pus, which formed a paste. He filled the wound with paste and covered it with tin. He next used as a dressing for all wounds antiseptic putty, made of carbolic acid, linseed oil, and carbonate of lime. The putty was found unwieldy and he used "antiseptic lac plaster," which is made by melting shellac and mixing it with carbolic acid. Its adhesiveness was highly objectionable, and he overcame it by painting the calico, saturated with shellac and carbolic acid, with "a solution of india rubber and benzine." The benzine was soon evaporated and the india rubber prevented the dressing from sticking. To prevent the irritation of the acid, he covered the line of incision with an oiled silk protective, which had previously been dipped in a solution of carbolic acid. We learn from Sir Hector Cameron that this was Lister's dressing when he returned to Edinburgh in 1869 as a successor to Mr. Syme. In the Lister number of the *British Medical Journal* Mr. Cheyne also has an article, in which he states that Lord Lister in 1873 substituted carbolic gauze for lac plaster and introduced his spray. In 1890, when he discovered that the dust did not contain pathogenic microorganisms, he discarded the carbolic spray, washed the wound with a weak solution of bichloride of mercury, and substituted the double cyanide of mercury and zinc for the carbolic gauze. He used carbolic acid for disinfection of the skin and instruments. Just prior to his discovery, from 1864 to 1867, his mortality in major amputations was 50 per cent. From 1867 to 1869 his mortality in the same class of cases was 15 per cent. In the face of these decisive and incontrovertible statistics, Spence, Billroth, and other leading surgeons ignored his teaching and continued to empty their wards with a death rate four times greater than his, until Professor Ogston of Edinburgh accepted it in its entirety, and he was soon afterward followed by Macewen of Glasgow.

At the age of eighty-four, poised and balanced, Lord Lister has reached the realization of hope and desire .the ultima thule of human endeavors, and the completion of a work that seemingly would exhaust the brain of a god. A son of a member of the Society of Friends, he is the antipode of his twin brother in science, the polemical, pugnacious, and unpeaceful Pasteur. When taunted and told at the British Medical Association at Plymouth in 1871 that "as his solutions became weaker and weaker his faith appeared to grow stronger and stronger," he did not swerve; he did not turn; but "intrepidly walked the highway of the right." Never aggressive; never palestric nor unpeaceful, but always kind and always considerate, he would say to his students, "Gentlemen, I commend these facts to your candid and impartial judgment, beseeching you to form your own opinions regarding them. You are as competent as you will be to draw logical inferences from established data." By his great generalizations he has placed every organ in the body under the domain of surgical sway, made possible the wonderful clinics of the Mayos, Murphy, Deaver, Ochsner, Robert Jones, and others. He has given an opportunity to this great discoverer, who has honored us with his presence here today, "who has sailed the unknown seas and found continents of surgical truths," whose name will live in connection with the surgery of the blood-vessels as long as surgery is taught as a science and practised as an art—Rudolph Matas. Lord Lister has relegated diseases like hospital gangrene to the past, and to victims, "oft in the morn and liquid dew of youth," listlessly looking a last good-bye to their loved ones he has given a chance, and glorified surgery. He has made civilized man his debtor, brought joy and gladness alike to the hovel of the poor and the palace of the rich, to the Coburg of Windsor Castle and the degraded occupant of White Chapel. When Baron Lister shall be no more, when he shall have "left the shore touched by the mysterious sea that never yet has borne on any wave the image of a homeward sail," the great surrogate of truth and justice will decree as his legacy to his profession the magnificent achievements of the present and the marvelous possibilities of the future. As over John Hunter, the organ in Westminster Abbey, where death is associated with public veneration and imperishable renown, will proclaim the chorus from Handel's Funeral Anthem:

"His body is buried in peace:
But his name liveth evermore."

Acute Influenzal Arthritis.—Ghedini reports a case of multiple arthritis in which the joints most markedly affected were the sternoclavicular and temporomandibular. These were red, painful, and swollen. Influenza bacilli were isolated from the blood. There were hardly any catarrhal manifestations. The disease ran a mild course, and recovery was complete in four weeks.—*Gazzetta degli Ospedali.*

The Method of Larat in the Treatment of Post-Diphtheritic Paralysis of the Palate.—G. Fumarola gives the histories of five cases treated with excellent results by the method of Larat for electrical treatment of postdiphtheritic paralysis of the palate. This form of paralysis is less frequent than before the use of antitoxin, yet it occurs in about one-half of the cases of paralysis. It is the result of the penetration of the toxin along the peripheral nerves backward toward the medulla. There is a degeneration of the radicular and bulbar nuclei. It occurs only in cases of pharyngeal diphtheria, showing that it is directly related to the location of the membrane. It occurs one or two weeks after the disappearance of the membrane. In the method of Larat faradism is applied by means of an electrode placed in a basin of water in which the child immerses the hands, while the other electrode is placed at the nape of the neck. The application causes no pain or apprehension to the child, as is the case when the current is applied directly to the palate.—*Il Policlinico.*

ATHLETICS AND ENDURANCE.

THE advantage of avoiding athletics seems to be the lesson to be drawn from a remarkable test of endurance and strength in Kankakee, Ill., in 1907, described by Dr. C. F. Langworthy, of the U. S. Agricultural Department, in *Science* of May 5, 1911. The contestants were to walk ten miles, each carrying a sack of sand weighing 100 pounds—not so very severe a test, by the way, as soldiers in war not infrequently cover more than 20 miles with a 75-pound load. Forty-eight started over a course which required 12 laps to make the distance; 4 dropped out in the first lap, 19 in the second, 3 in the third, 3 in the fourth, 4 in the fifth, 2 in the sixth, 2 in the seventh, and 5 in the eighth, ninth, tenth, eleventh, and twelfth, only 6 finishing. Langworthy communicated with the contestants to find out whether their habitual diet had any bearing on the result and found nothing noteworthy as to the kind of foods. The surprising thing elicited from four of the winners was the vigor resulting from the ordinary muscular labor of the daily employments, each stating that his work involved muscular activity, but only one stated what it was—"shipping clerk in a retail grocery." We can presume that none of them was accustomed to severe muscular strains or the test would have been child's play. One of the clerks, aged 24, stated that he was fond of athletics and walked to and from work, 1¼ miles, 4 times daily, and had had training in the National Guard, but he omitted mention of any athletics permissible for a busy grocery clerk. The second, aged 40, had not engaged in athletics since he was 18. The third, aged 52, had not engaged regularly in any athletic exercises. The fourth, aged 21, was not fond of athletics and did not keep in training. This last man said he ate a medium amount, whatever that might mean, and the other three were "hearty eaters"—facts we would call to the attention of those dietetic faddists who have been apparently trying to prove that the less one eats the more strength and endurance he has. The really important lesson is the fact that men 40 to 52 years of age retained strength and endurance more than necessary for soldiers in war, and did it without athletics or training of any kind, but merely by their daily labor, which we presume was never excessive in length or amount or it would have been given as the reason for success. This test should be seriously considered by those athletic enthusiasts of our army and navy who seem to think that marching ability is not possible without strenuous training. So many contend that such exercises reduce endurance that we would suggest, in the interests of military efficiency, that the matter be tried out. Let two or three regiments be given only as light drills and exercises as the grocery clerk, and be never fatigued. Let two or three others be given a severe course of training with frequent practice marches heavily loaded. Then after a year, say, compare their ability to cover 200 miles. The Kankakee test would indicate that the former would be the better marchers.

It is to be regretted we did not learn how many of the failures in the test were "trained" men who had run the athletic pace which kills. It would also have shed some light on the canteen controversy to have learned whether there were any beer drinkers among the winners or losers. So far as the evidence goes it seems that men have better health, strength, and endurance if they indulge moderately all natural appetites, starve none of them, nor indulge them to excess. The strenuous athletic life is apparently giving way to a common sense life, but it doesn't give way very quickly.

A NEGLECTED OPPORTUNITY.

FOR almost twenty years immigrants from all parts of Europe have been pouring into this country under conditions and supervision by governmental authorities which should readily lend themselves to the collection of a vast amount of important anthropometric data. It would seem, with almost 1,000,000 new arrivals every year, that in the course of a decade the biometrician could have at his command a sufficiently large number of observations to be of great use to the trained anthropologist of the next generation. The study of the racial type which is now evolving in America could thus be put on an accurate scientific basis and the data collected to-day would be available to the student of eugenics and heredity in the future. The exact measurement of the skull and body and the recording of the color of eyes and hair and the degree of blondness, or the contrary, of every arriving immigrant would go largely toward establishing the physical pedigree of the future race. If these data were collected now and handed down as a gift to posterity, it would go far toward placing the study of eugenics upon an exact scientific basis, for the value of this kind of investigation has been clearly established. In the *Popular Science Monthly*, for August, J. Arthur Harris concludes a very appreciative article on Francis Galton with the statement that "Galton and his school have shown that in our strenuous modern life the statistician can point to some factors which tend to conserve and to others which tend to destroy the type of men which have made a high civilization possible, and they have told us in ringing words that it is the duty of the man of science to apply the most rigorously exact methods to the investigation of all those factors which tend to improve or impair the racial qualities of the generations yet unborn."

At the instigation of the immigration commission appointed during the Roosevelt administration, Prof. Boaz collected quite a large amount of data relative to the head forms of immigrants and their posterity, but the work thus barely commenced has been allowed to drop. We see no reason why it should not be taken up again by the officers of the Public Health and Marine-Hospital Service. As they already number the medical examination of immigrants among their duties it would be a natural step for them to establish a school for biometricians at Ellis Island and by the data thus collected the study of racial conservation would be advanced without in any way interfering with the more pressing present duty of preserving the public health.

NUCLEIN METABOLISM.

Our knowledge of metabolism appears to be undergoing a steady increase, provided we distinguish carefully between facts and hypotheses. If we attempt to account for the exact sources of blood and tissue albumins, body fats, and animal sugars and starches, we become involved in hopeless controversies. On the other hand, if we proceed from one series of known facts to new facts, the advance in knowledge is so remarkable that we feel assured of the ultimate solution of all metabolic problems. This steady increase in our knowledge is well shown by Stephan, who read a paper last March before the Verein der Aerzte Wiesbaden (*Berliner klinische Wochenschrift,* May 8) on nuclein metabolism. The subject is an important one because of the relationship of nuclein to uric acid. Endogenous uric acid is derived from the metabolism of the organ cells, exogenous uric acid from the nucleins and purin bases of the diet. Uric acid has been oxidized to urea by alkaline solutions of hydrogen peroxide and has been decomposed by radium emanations into ammonia and carbonic acid.

Nuclein occurs in the nuclei of cells as nucleoproteins, which consist of nucleinic acid and two albumin components, one of which splits up readily, the other with difficulty. Nucleinic acid is a tetrametaphosphoric acid in which each phosphorus atom is associated with a carbohydrate (hexose). When nucleoproteins of the diet reach the stomach they are split into albumins and nuclein. The latter is now attacked by trypsin and decomposed into nucleinic acid and cleavage products with a change of nature from the colloid to the dialysable, soluble, and absorbable state. Behind the intestinal epithelia the nucleinic acid is attacked by powerful ferments, which have the power to change it to uric acid. Some of it, however, must go to rebuild the nucleoproteins of the organ cells. The proximal cleavage products are oxypurins. The enzymes which convert nucleinic acid to the latter and uric acid are respectively nuclease, which first breaks up the acid molecule; purindesamidase, which forms oxy- and diozypurins (xanthin) with liberation of ammonia; xanthinoxydase, which changes oxypurin to xanthin and uric acid, and uricöoxydase which changes uric acid to allantoin (this transformation has not yet been proved to take place in man).

Stephan's paper was well discussed. Pfeiffer stated that the existence of uric acid in considerable amounts in healthy blood had now been proven. The percentage is increased by acids (HCl) and diminished by alkalies. Weintraud appeared to admit that the difference in this respect between gouty and healthy blood was probably one of degree, although it may be shown some day that uric acid in gouty blood is bound in a peculiar manner. The advances in our knowledge in this field show that the semi-empirical remedies for gout and allied conditions—diet, oxidation, and alkalies—have a rational basis. To these has recently been added radium emanations, which, as we have seen, are able to break up uric acid into its elements.

NATIONAL INSURANCE LEGISLATION IN GERMANY.

While the British government is seeking to rush through the House of Commons its elaborate program of national insurance, the German Reichstag is debating over the proper revision and extension of the German system of State insurance, whose apparently successful operation has stimulated the efforts of Chancellor Lloyd George and his associates. It would appear as if the fears of the British profession regarding their own hardships under the proposed law are justified by the experience of their colleagues under the law now in force in Germany. Not only have the complaints and petitions of the German profession been disregarded, but in addition the benefits of the proposed law are to be extended so as to include a larger number of people. The income limit for those eligible to the benefits of health insurance is to be raised from 2,000 to 2,500 marks; while children will be insured under the new law. Both of these provisions will tend materially to decrease the income of physicians.

It would seem as if imposing schemes of social betterment cannot be inaugurated without working some hardships to special classes, and perhaps members of the medical profession will be compelled to submit to the curtailment of their own revenues, though it is fairly safe to predict that this will result ultimately in lowering the standards and diminishing the ardor of medical men.

In spite of the fact that the new German legislation, as related by our Berlin correspondent, ignores the just demands of those who bear the brunt of battle against the foes of health, a brief review of some of the provisions of the new law indicates its wide and beneficent scope: the granting of invalidity insurance to all of the working classes, urban and rural, including those changing their place of employment at frequent intervals no less than those permanently employed in one locality; including teachers, domestics, and those employed in dramatic and musical organizations. The maternity benefit, which is such a striking feature of the proposed British law has also been included in the proposed new German legislation, while the annuities for widows and orphans and the endowments for the latter testify to the growing paternalism and philanthropy of the State.

SANATORIUM TREATMENT FOR PULMONARY TUBERCULOSIS.

The national insurance scheme of Mr. Lloyd George includes the treatment of pulmonary tuberculosis on an unprecedented scale. It certainly appears, from the manner in which he proposes to deal with the disease, that he cannot have sought the advice of experts on the subject. According to reports which have reached this country, the British Chancellor of the Exchequer seems to hold the view that sanatoria are the only effective means of coping with the disease. That such a view is in a high degree fallacious is obvious to all those who have kept in touch with the most recent opinions delivered on the matter. In truth, it is now fully recognized that sanatorium treatment of consumptives has its very definite limitations and it is not even certain that, in some respects at least, the benefits of sanatorium treatment have not been greatly exaggerated, and that home treatment, when the conditions are favorable and even when they are not altogether so, may not in many cases be productive of better results, at least so far as the so-called economic cure is concerned.

At the meeting of the American Climatological Association, held recently in Montreal, the question of the treatment of pulmonary tuberculosis was threshed out in a fairly thorough manner, and incidentally some doubt was cast on the success of sanatorium treatment. In the first instance, in the case of working people sanatorium treatment cannot, as a rule, be carried out properly. Wage-earners with limited means cannot afford to stay in a sanatorium sufficiently long to effect a cure. Further, in the early stages of the disease, the only period in which a cure can be looked for with any degree of certainty, treatment so far as the working classes is concerned is either lacking owing to a diagnosis not having been made, or the sufferer refuses to leave his family to go to a sanatorium in the country. At the Montreal meeting the various methods employed for treating tuberculosis were discussed and the general sentiment of the meeting appeared to be that dispensaries, sanatoria, and hospitals were all essential in the crusade against tuberculosis.

There are two points, however, which stand out conspicuously when discussing the treatment of tuberculosis with a view to its ultimate eradication, and these are that in order to cure the disease the patient must be properly treated in the incipient stage, and that in order to prevent the spread of the disease those in an advanced stage must be isolated. For the treatment of incipient cases dispensaries and sanatoria both appear to be needed, while in the case of those suffering from tuberculosis in an advanced stage the main object is to prevent infection being spread, and this can be effected by the establishment of isolation hospitals near all towns. The total abolition of pulmonary tuberculosis will tax to the utmost the brains and energies of the most able and earnest medical authorities of every country, and the problem will not be solved by the establishment of sanatoria alone, however numerous and well equipped they may be.

Source of Urobilin.

Urobilinuria has long been known to signify hepatic insufficiency, since urobilin should be destroyed by the normal action of the liver. This knowledge, however, is of little practical value because urobilinuria occurs under the most varied conditions, trivial as well as severe. To understand the phenomenon we should be able to trace urobilin back to its ultimate sources, and this has hitherto been impracticable. At a recent session of the Verein für innere Medizin und Kinderheilkunde, Berlin (*Muenchener meizinische Wochenschrift,* June 20), Brugsch announced that thanks to Ehrlich's dimethylamidobenzaldehyde the various steps in the formation of urobilin could be successfully traced. Urobilinuria is invariably associated with urobilin in the feces. The more urobilin in the urine the greater the content of the substance in the feces. The amount in the latter naturally varies with the amount present in fresh bile, and the amount formed in the intestine from biliary coloring matters. The liver in disposing of used up blood corpuscles forms urobilin from hematin, and urobilin is therefore spoken of as blood slag or cinders. There may be more blood slag at one time than another, since more blood may require destruction. As a matter of fact, however, urobilin is more or less an incidental stage in the promotion of biluribin, and its presence in excess simply indicates that the liver has for some reason failed to convert it. In all diffuse affections of the liver it appears in the intestine in large amounts and thus gives rise to urobilinuria. The practical significance of urobilinuria as an exponent of the action of the liver is marred, however, by the fact that urobilin may appear in the feces in large amounts as a result of the action of putrefactive bacteria on the biliary coloring matters. Not over 25 per cent. of the latter escapes by the rectum. It is now well known that certain saprophytes, and even pathogenic bacteria have a special property of forming urobilin from the coloring matters, and this test may be employed in laboratory work for differentiation. From all that has been said, therefore, it does not seem at all likely that urobilinuria will ever possess any exact significance in the estimation of the work of the liver. But if increased intestinal putrefaction can be excluded the symptom possesses relative value.

Diathermy.

Diathermy, otherwise known as thermopenetration, the warming of internal organs between the electrodes of an alternating induced current, is a therapeutic resource of such promise that it was made the subject of a symposium at the recent meeting of the German Congress for Internal Medicine (*Münchener medizinische Wochenschrift,* May 16). Rautenberg spoke straightway of the diseases seemingly benefited by the current. In heart disease with dropsy the latter was seen to disappear with profuse diuresis, while the heart seemed sensibilized to the action of digitalis. Attacks of angina pectoris became fewer and sometimes disappeared. In bronchitis and bronchopneumonia expectoration was facilitated, while pleural exudates were absorbed. The temperature of organs between the electrodes may rise as high as 41° C. When thermopenetration is applied over the larynx the mirror shows after twenty minutes a reddening of

the vocal cords with hoarseness. The sense of increased warmth is pleasant. Stein stated that the most important indications for thermopenetration were acute gonorrheal rheumatism, acute gout, and ordinary acute rheumatism. The tissues were also sensibilised to the action of radium emanations. The method was not applicable to the abdominal viscera. According to Schittenhelm the general body temperature of a hound may be greatly elevated by an hour's exposure. Bennecke praised thermopenetration for gonorrheal rheumatism. Pleuritic and pericardial murmurs appearing after the use of the remedy do not signify that exudates have been absorbed, but are due to direct heat injury of the serosæ. Reicher thought that diathermy of the bone marrow should influence favorably certain blood diseases of myelogenous origin. Warburg was somewhat sceptical as to the character of the results reported but found the resource of value in neuralgia. Stein spoke of the value of diathermy in lupus vulgaris. In addition to his paper read at the meeting of the internists, Stein also appeared before the German Surgical Society and informed that body that the term diathermy signified only a variation of the high frequency current, the vibrations not being deadened, as in the latter. The alternations occur at the rate of a million per second. This current, in its passage through the body, heats the viscera, and with sufficient dosage is able to destroy the latter. A special apparatus and technique are required to control the current and render it free from danger. The author has treated seventy cases of bone and joint disease, and has obtained striking results in acute gonorrheal arthritis and acute gout, chronic gout, simple chronic rheumatism, and acute periostitis.

News of the Week.

Vital Statistics.—For the week ending August 5 the Department of Health of New York City announces that the death rate is the lowest on record for that week since the formation of the Greater City in 1898. The death rate of 14.10 is 15 per cent. lower than the lowest corresponding week for the past thirteen years and 23 per cent. lower than for the corresponding week of last year. The infant mortality under one year of age was 156 per 1,000 in the week as against 235 per 1,000 for the corresponding week of last year, a decrease of 32 per cent. The infant death rate from diarrheal diseases was almost 50 per cent. less during the week than for the corresponding week of 1910

Scores Antivivisection.—King Frederick of Denmark refused to give his patronage to the International Animal Protection and Anti-Vivisecting Congress, which has been in session in Copenhagen, upon the ground that he could not bestow his support upon a body which was opposed to scientific methods of research. Thereupon the members of the Cabinet likewise refused to become patrons of the congress.

Pellagra in Kentucky.—Following the discovery of seventeen cases of pellagra in the Eastern Kentucky Insane Asylum, upwards of one hundred cases have been found in Bell and Whitely counties. The State Board of Health has called a meeting, which will be held on August 9, to which experts from the government and the Rockefeller Institute have been invited.

Find Pasteurization Necessary.—Commissioner Lederle of the New York City Health Department has come out with the statement that it is utterly impossible to have 44,000 farms, in seven States, sending 2,000,000 quarts of milk daily to the city properly and adequately inspected, and that as an assurance of a pure milk supply inspection has failed. The department has therefore issued a formal order that beginning on January 1 next practically all milk for general use in the city must be pasteurized in a manner to be indicated by the Board of Health. Two classes of milk will be exempt from pasteurization, the "certified" milk and that which is used for cooking purposes exclusively.

Anti-Smokers Incorporate.—The Non-Smokers Protective League of America, having its principal office in New York City, has filed papers of incorporation with the Secretary of New York State. The league will attempt to encourage and insist on the enforcement of laws, ordinances, and regulations restricting smoking. Dr. Harvey W. Wiley of Washington, David Starr Jordan of Leland Stanford University, and a number of individuals prominent in educational work are among the directors.

Degrees for Americans.—At the centenary celebration of the University of Breslau which took place on August 3, honorary degrees were conferred upon Dr. Nicholas Murray Butler of Columbia University, Dr. Charles W. Eliot of Harvard, Dr. Theobald Smith of Cornell and Harvard, and Dr. Benjamin Wisner Bacon of Yale.

The International Stomatological Congress was held last week in Paris. Among those who read papers were Drs. Richter of Milwaukee, Cryer of Philadelphia, Bogue of New York, and Talbot of Philadelphia.

New Hospital for Boston.—The construction of the Peter Bent Brigham Hospital has been begun. This institution will consist of fourteen buildings which will cost $5,000,000 and will be closely associated with the Harvard Medical School. Dr. Herbert B. Howard will be the Resident Physician, Dr. Harvey W. Cushing of Johns Hopkins Hospital, Baltimore, will be Surgeon-in-Chief, and Dr. Henry A. Christian, Dean of the Harvard Medical School, will be Physician-in-Chief.

Fire in an Insane Asylum.—Eight lives were lost in a fire that partly destroyed one of the main buildings of the Insane Asylum at Hamilton, Ontario.

An Opportunity to Study Baby Saving.—The Committee for the Reduction of Infant Mortality of the New York Milk Committee has extended an invitation to 3,500 students, mostly teachers, now attending the summer schools at New York University, and also to 3,000 mayors, health officers, and other city officials in every part of the United States to spend a day in studying the methods employed in this city for caring for babies during the hot season.

Will Not Take the Mayor's Money.—A hearing was recently held in New York City on a bill providing for the payment of the bills of the surgeons who attended Mayor Gaynor after he was shot last summer. The Mayor said that he had never asked that the bill be drawn, but that the surgeons had absolutely refused to render him a bill and would never be paid unless by the city. The bill also provides for the payment of the surgeons' bills in the event of any similar accident to any city employee.

Changes in the Medical Staff of the Department of Charities.—Dr. Walter Conley has been

appointed deputy superintendent of the Metropolitan Hospital on Blackwells Island to succeed Dr. William H. Polglase who has been put in charge of the Cumberland Street Hospital in Brooklyn. Dr. John T. Fitzgerald, formerly medical superintendent in Brooklyn, has been made general superintendent of the Public Charities Commission Hospitals at a salary of $6,000. Dr. J. F. Scofield becomes a deputy superintendent of the Coney Island Hospital.

Ambulance Accident.—In a collision between a Bellevue ambulance and a street car last week, Dr. Cody, the ambulance surgeon, was seriously injured and the ambulance badly damaged while the patient escaped uninjured.

Dr. James V. May of Binghamton, N. Y., has been appointed by the Superintendent of State Prisons medical superintendent of Mattewan State Hospital for the Criminal Insane *vice* Dr. Robert B. Lamb, resigned.

Pennsylvania State Board of Medical Examiners.—At the June examination held by this board 395 candidates presented themselves, of whom 377 passed and 18 failed, a percentage of failure of only 4.55.

Medical Registration in Barbados.—The Legislature of Barbados, B. W. I., has recently revised the Medical Registration Act of that colony. Eligibility for registration on the part of an American graduate (in any State) desiring to practise in that colony, is based on the applicant's presenting the New York State Board License, and certifying to the medical assessors the fact of being a registered practitioner in New York. A New York physician visited Barbados in the spring of 1910 and there registered, his license being the first presented from this State.

Bequests to Charity.—The will of the late Simon E. Bernheim gives $2,500 to each of the following institutions: Hebrew Orphan Asylum, Montefiore Home, Mount Sinai Hospital, Home for Aged and Infirm Hebrews, and the German Hospital.

The will of the late E. C. Whitney of New York contains a bequest of $5,000 to endow a bed in the Orthopedic Hospital.

Obituary Notes.—Dr. Milton A. Piper of Philadelphia, a graduate of Princeton University in 1869 and of Jefferson Medical College in 1871, died on July 27, aged 56 years.

Dr. William Burd Evans of Philadelphia, a graduate of the Maryland Medical College in 1902, died on July 28, aged 33 years.

Dr. Fred Albert of Mason City, Iowa, a graduate of the University of Iowa College of Medicine in 1906, assistant in bacteriology and pathology in the college, and associate bacteriologist to the Iowa State Board of Health, a member of the Iowa State and Cerro-Gordo County medical societies, and the Austin Flint-Cedar Valley Medical Association, and president of the Iowa State Association of Health Officers, died at his home of typhoid fever on July 21, aged 30 years.

Dr. Hubbard Linley of Atchison, Kan., a graduate of the University of Nebraska College of Medicine in 1893, a member of the American Medical Association, the Kansas State and Atchison County medical societies, the Tri-State Medical Society, and the Medical Society of Illinois and Iowa, and surgeon to St. Francis' Hospital, Atchison, died suddenly in his office on July 14, aged 51 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COMING MEETING OF THE MEDICAL ASSOCIATION AT BIRMINGHAM—CONFERENCE OF THE NATIONAL ASSOCIATION FOR PREVENTION OF CONSUMPTION—CANCER RESEARCH.

London, July 21, 1911.

So many doctors are now "out of town" or "abroad" that there seems a determination to make the most of the magnificent summer weather we are enjoying—such a contrast to that of last year. Some who do not like early holidays will begin next week with the Birmingham meeting, and after that take their trips. You know that the British Medical Association occupies most of next week with its annual meeting, and that it will be at Birmingham. In a sense the meeting begins to-day, for the representatives of the branches and the council meet this morning and dine together this evening. To-morrow the "representative meeting" will receive the report of council and discuss other matters concerning what may be termed the domestic affairs of the association, and which are not supposed to interest others than members. This meeting, which we familiarly call the "caucus," does, however, practically determine the policy to be adopted, and matters of public interest often occupy it. This year the insurance bill will no doubt be freely discussed. You see, the arrangement is well adapted to keep the power in the hands of the few—the council and its most active members—for only those delegates who are its supporters are likely to take a week-end extra at the meeting place, and the caucus can carry almost any resolutions the wire pullers desire. It is an improvement on the management of old time, when these wire pullers dined together after the general meeting, and sometimes, as at Brighton, actually reversed the decision. But the name representative must be accepted *cum grano salis*.

The real general meeting will open on Tuesday, when the president will deliver an address. The rest of the week will be occupied by the sections in which a full number of papers and discussions are in store. There is to be, as usual, an exhibition of drugs, foods, instruments, etc., as well as various amusements, excursions, and the other attractions which form the popular background of these scientific-medical assemblies.

Wednesday, yesterday, and to-day, the National Association for Prevention of Consumption has been discussing—a little prematurely, perhaps—the best ways of employing the money to be granted by the insurance bill for dealing with tuberculosis. The discussion is carried on in five sections: (1) Education, (2) machinery of detection, (3) treatment, (4) after-care, (5) administrative and financial aspects of the bill. An exhibition has been opened simultaneously of charts, models, and other material which has been on tour in various parts of the country.

At the opening meeting a message from the King as patron of the association was received, congratulating all taking part in the conference and saying, "I sympathize deeply with the work, so farreaching in its influence on the future of the human race."

An address was delivered by Mr. John Burns, who quoted a number of statistics in support of an optimistic conclusion that tuberculosis is a declining disease, and its annihilation will be effected in this generation. Coincidentally, he said the drink

bill of the people had diminished by 25 per cent. per head. He mentioned this because Brouardel had said, "The public house is the purveyor of consumption," a view supported by Niven of Manchester and other authorities. Referring to the Royal Commission's report, he said he had a "milk bill ready" if it could be an agreed one, but if not it would not be got through Parliament this session.

Prof. Sims Woodhead pleaded for the teaching of hygiene in schools. No doubt bad housing, poverty, malnutrition, fatigue, want of fresh air, and uncleanliness were all factors in predisposing to the disease. All were important. If one were got rid of another might remain, *e.g.* poverty without alcoholism was less dangerous than with it.

Dr. Shrubshall read a paper on the place of the school in the campaign, in which he gave an account of the teaching and enforcement of personal hygiene in schools. The most effective guard against consumption, and, indeed, all other infectious diseases, was to cut down the means of dissemination. This really meant cleanliness in all things. A child taught to be clean would continue the habit afterward, and school was the training ground for a national health conscience.

Sir William Younger said exhibitions and caravans preached the gospel of fresh air, sunshine, and healthy surroundings. They showed healthy people how to arm themselves against the insidious foe, and taught sufferers how to live. They also showed how the question of housing was bound up with prevention.

Dr. Philip of the Edinburgh Royal Infirmary opened the second part of the conference—the machinery of detection—with the statement that tuberculosis in the adult was generally developed from the disease in the child. Every intelligent person was of detective value, and school was a training ground for scholars to become detectives. He urged that a case discovered should lead to attention to the whole family. Compulsory notification was adopted by seventy-four local authorities in Scotland in 1910, but in 1907 in only eight. The tuberculosis dispensaries lately set up in London he considered of the utmost value, and linking them up in a central council was a statesmanlike policy.

Dr. Cecil Wall of the London Hospital took up the question of out-patients, and said if the insurance bill became law hospitals would be affected gravely. At the London at least a third of the present patients would be taken away. If it passed unaltered the only persons unprovided with free medical attendance would be children under school age, unemployed persons from fourteen to sixteen years old, unemployed women, and persons over seventy. As to the insured, out-patient department, general and special, would retain only consultative functions.

Dr. Halliday Sutherland said the tuberculin dispensaries made a triple attack on the disease: treatment from the center, selection for open air methods, and search for early and undiagnosed cases.

Dr. J. Niven, medical health officer for Manchester, described the work carried on in that city, and offered valuable suggestions in connection with notification and the insurance bill.

Yesterday the subject of treatment occupied the whole day. Sir Douglas Powell opened the proceedings. He said there were two groups of cases—the annual new ones, and the residual ones of the population. The more successfully they dealt with the former the fewer would go to swell the latter, as death was always busy in removing these. It might be that immunity, acquired and hereditary, would lessen the proclivity to the disease among survivors.

Sir William Osler warned against the notion that everyone with a little deviation from normal health was tuberculous. If tuberculin was made a final test of correct diagnosis figures as to treatment would be useless, for improvement was seen under any or no treatment. Probably not 10 per cent. should go to a sanatorium, and they must elaborate home treatment. He pleaded for the association of tuberculin dispensaries with general hospitals, and dreaded the growth of a group of men whose whole work was in the dispensaries, for they must necessarily become narrow. Undoubtedly tuberculin was an efficacious remedy in suitable cases, and in a few years they would know definitely which were such.

Dr. Arthur Latham said the public had not grasped the facts about sanatorium treatment; that in many cases it must be useless, in a few actually harmful, and in many it need not be carried out in an institution. In the majority of these the treatment was inefficient, namely, fresh air and free feeding. The cardinal factor was constant, skilled regulation of the amount of rest and exercise prescribed from day to day for each individual patient.

Dr. Paterson, superintendent of the Friendly Sanatorium, urged the importance of teaching the patients. How his patients appreciated this was proved, he said, by the fact that they bought sputum flasks when they left at 4 shillings each, and some stole the flasks of other patients. Unless they meant to follow out the treatment they had had they would not part with money or break commandments.

Dr. Edward Squire spoke of the insurance bill, and said its provisions were futile for checking the disease. There was no power to remove a patient who was dangerous to family and others. Home treatment meant more than prescribing drugs or injecting tuberculin. It included care for the contacts.

Dr. Sykes, medical health officer, advocated the cooperation between philanthropic and municipal agencies in the first stage, especially in persons under sixteen, for whose benefit the children's act might be utilized.

Prof. Ralph Williams of the University of Sheffield told of the open air school established there. Of ninety-eight children in it forty-four were cured, fifty-one improved, only three in the same state as before admission. The drawback of these schools was that after a few weeks or months the children went back to the other schools and lost what they had gained.

Dr. A. M. Williamson, medical health officer for Edinburgh, said that there 59 per cent. of cases were in two-roomed houses, and 93 per cent. in houses with four or fewer rooms. Segregation of advanced cases was useless without notification. He urged attractive hospital accommodation for these in combination with shelters and pavilions in the open air.

Dr. Woods Hutchinson, New York, said the sanatorium represented the one-hundred-ton gun in the campaign. But campaigns were not to be won by one-hundred-ton guns. It was not necessary to build institutions to last one hundred and fifty years when they hoped to wipe out the disease in thirty years, and they had no desire to immortalize the disease. In New York ten thousand died of

consumption every year, and twenty-two thousand new cases were recorded. This showed each advanced case infected two others. If he had to choose between segregation of early or advanced cases he would select the latter.

Other speakers discussed various points as to segregation, notification, and the difficulties that would certainly be raised by the public in regard to these measures. Education was therefore much insisted on, so was cooperation between the existing authorities and those proposed to be set up under the insurance scheme.

To-day the conference concludes with a discussion on the administrative and financial aspects of the bill.

A large number of visitors attended the "annual viewday" at the sanatorium connected with the Brompton Hospital, which contains one hundred and fifty beds, and is always full. The institution has been at work about seven years for treatment by open air combined with carefully graduated exercise, or work. About three hundred ex-patients attended, and their appearance gave evidence of the success of the system.

Yesterday the Imperial Cancer Research Fund's annual meeting was held in the Royal College of Surgeons. The results of experiment and observation were stated in the report, and in speeches by Sir William Church and Sir H. Morris.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

NEW GERMAN NATIONAL INSURANCE LEGISLATION—HARDSHIPS OF THE MEDICAL PROFESSION UNDER THE OPERATION OF THE STATE INSURANCE LAWS—BROADENING OF THE SCOPE OF THE NEW LAWS—ANNUITIES FOR WIDOWS AND ORPHANS.

BERLIN, June 15, 1911.

DURING the past few weeks the interest of the entire German profession has been centered on the Reichstag, where the prolonged debate on the Government's insurance scheme is drawing to a close. This law with its 1,700 paragraphs constitutes the most extensive law that has ever been placed upon the statute books. Considering the many millions of people who are subject to the benefits of this law, it is the medical profession that is at this moment most concerned in the fate of this legislation. What would be the outcome of the passage of this law? One can definitely state the outcome only so far as the doctors are concerned. The medical profession shows evidence of its own disillusion regarding its status under former operations of the State insurance measure. For years the profession has written memorials and petitioned the Government as regards its hardships under this law, and has sought to have its demands satisfied by a revision of this law. And now it is our lot to behold that no one has cared an iota about the wishes of the doctors, for the fate of insurance legislation has been determined largely by political motives rather than the interests of the people. So far as the medical profession is concerned not only are the former abuses undisturbed, but an additional hardship is added, namely, the income limit for those eligible to the benefits of health insurance has been raised from 2,000 to 2,500 marks. As a result of this change there will be admitted to the ranks of beneficiaries a large number who have hitherto stood in close and profitable relationship with their private physicians.

The proposed insurance law affects three former kinds of insurance—the sickness, accident, and invalidity insurance. In addition there is now to be included the insurance of surviving widows and orphans. The main work will be carried out by the insurance offices that will be established by the minor government authorities and the local boards. There will be two large groups of compulsory invalidity insurance. The first of these comprises the general group to which the local and the rural forms belong. The rural insurance includes the farmhands and the forest laborers, the domestics, those who are not employed long in one place, and those employed in work about the house. To the second group belong the special classes of compulsory insurance, the fraternal bodies, the workmen's compensation insurance, and the miner's mutual benefit societies associated with both the mining and smelting industries. While formerly the provisions of the State insurance law applied only to certain designated industries, the new statutes will apply to all persons employed in subordinate and dependent positions. There will now be included all the agricultural and forestry employees, all domestics, peddlers, home-workers, druggists' assistants and apprentices, teachers and governesses, and those employed in the dramatic and musical industries.

If a person happens to be a member of the sick fund and increases his income beyond the limit of 2,500 marks, he nevertheless has the right to continue his membership. The trials of the medical profession under the operation of this law will be discussed more at length in my next letter. A new provision is that of a maternity benefit. Every insured woman in the event of childbirth will be entitled to financial assistance for a period of several weeks.

Under the new law, as under the old, two-thirds of the premiums are to be paid by the employers, while one-third is to be paid by the employees. While formerly the directors of the insurance company have been elected by the employees, under the newly proposed law the conditions are reversed and this choice is to be exercised by the employers alone.

In the provisions relating to casualty insurance the benefits of the latter are to be extended to those earning as high an income as 5,000 marks; under the former law the limit having been fixed at 3,000 marks. Two forms of indemnity have been introduced: preliminary and permanent benefits. Within a period of two years following an accident a preliminary settlement may be made, but this may be changed at any time. At the end of two years the permanent benefit must be decided upon, but this may be adjusted anew every year. In the system of invalidity insurance a section has been introduced providing for the insurance of children. Another innovation is the eligibility of women to positions on the boards of directors and committees of the insurance organizations. The new provisions made for the benefit of widows and orphans comprise annuities for widows and orphans and endowments for the latter. These endowments, however, are not to be in the form of annuities but are to be made in one payment. Even though the sums allotted are small, nevertheless this provision represents a decided step in advance. The date proposed for the setting in force of the new law is January 1, 1912.

Progress of Medical Science.

"On Stiff and Painful Shoulders," as Explained by Subacromial Bursitis and Partial Rupture of the Tendon of the Supraspinatus. E. A. Codman.
Experimental Pneumectomy; the Application of Data so Obtained to the Surgery of the Human Thorax. W. C. Quinby and G. W. Morse.
Interlobar Exudates. A. K. Stone.
The Hemolytic Skin Reaction in Carcinoma. E. H. Risley.
The Chemical and Microscopic Findings with Reference to the Gastrointestinal Tract in Pernicious Anemia. A. E. Austin.
The Diagnosis and Treatment of Breast Abscess. W. P. Coues.

"Stiff and Painful Shoulders."—E. A. Codman states that these are so common and cause so much disability among the working classes that they deserve much more attention than has hitherto been given them. The intense pain which many cases suffer and the long duration of the condition make the question one of great importance, although the eventual outcome is quite sure to be favorable. It is the author's belief that the primary and important lesion in most cases is a slight tear of the fibers of the tendon of the supraspinatus just at its insertion in the greater tuberosity; that this lesion causes an irregularity on the base on the subacromial bursa, and hence a bursitis, which, either by inhibition due to pain in the early cases, or adhesions in the old cases, prevents the tuberosity from passing beneath the acromion and the coracoacromial ligament.

Experimental Pneumectomy.—W. C. Quinby and G. W. Morse, having shown that experimentally a lung may be excised with safety, and having examined the physiological factors which underlie such successful removal, discuss the application of such data to the human being. At the outset they find that any operation which includes the resection of any considerable amount of lung tissue must be planned with full recognition of the fact that, because of its firmer structure, the human mediastinum cannot be displaced nearly to the extent possible in the dog. The very important factor of obliteration of the remaining space in the thorax must thus be met almost wholly by resection of ribs. But such resection must be relatively limited in its extent, else support of the vital organs contained in the thorax is lost. Therefore, successful excision of lung tissue in man has been limited to one lobe at the most, and in such conditions as localized bronchiectasis a number of cures have followed this operation.

Interlobar Exudates.—A. K. Stone states that the signs of an encapsulated interlobar exudate of considerable size are: a zone of dullness, more or less high pitched and tympanitic in character, with presence of bronchovesicular breathing over the dull area, often accompanied with friction sounds, if the condition is acute; below the dull zone the resonance and respiratory sounds are more nearly normal; on the left the tympanitic area of the stomach (Traube's space) is retained and on full inspiration the more normal area below the zone of dulness increases in size; the dull triangle, the paravertebral triangle, in the opposite thoracic cavity is not present, as is usual in large, free exudates. If the exudate is on the right side the heart is apt to be extremely displaced to the left (A. Fraenkel); if on the left, the displacement is not so marked as with free fluid (Stone); the radiograph will show a shadow extending from the apex of the heart toward the head of the humerus, or from the sternal junction of the fourth rib on the right outward to the head of the humerus; the fluoroscope will show the same shadow band and also the diaphragm in motion. Small collections of pus are to be found by careful percussion and the presence of tender spots.

The Hemolytic Skin Reaction in Carcinoma.—E. H. Risley presents an analysis of a series of 100 cases in which the skin reaction test used by Elsberg for the diagnosis of carcinoma was done. The author concludes that the test is only suggestive and is rendered practically valueless as a diagnostic aid because of the fact that there are undoubtedly present in the blood of many patients other lysins of unknown nature which bring about hemolysis of varying degrees. This applies to the non-malignant cases giving a positive reaction.

The Gastrointestinal Tract in Pernicious Anemia.—A. E. Austin states that practically the only feature which remains constant in the feces of all pernicious anemias is the markedly increased amount of stercobilin. Another feature which marks these cases, in distinction to other anemias, and which also signifies the increased amount of stercobilin, is the rapidity with which the antecedent or mother substance, the so-called urobilinogen, is converted into the active pigment; ordinarily it takes twenty-four hours for corrosive sublimate to effect this conversion in a normal stool, but here the change takes place in a few hours, and even without the aid of the chemical when the stool is placed in the sunlight open to the air the change takes place with remarkable rapidity.

Breast Abscess.—W. P. Coues offers the following "don'ts" in connection with the treatment of breast abscess. (1) Do not open any but the most superficial breast abscess without gas or ether. You will hurt the patient and not do a thorough piece of work. (2) Do not drain any but the most superficial abscess with gauze or rubber tissue. Use a soft fenestrated rubber tube, and leave it in till all deep pus is out of the breast. (3) Do not irrigate a breast abscess. You will spread pus and organisms about inside the breast and do more harm than good. (4) Do not use peroxide of hydrogen in a breast abscess, as it will act in the same way and tend to spread infection rather than to lessen it.

New York Medical Journal.

Prostatic Suggestions.—V. C. Pedersen states that the proper time for operation in cases of enlarged prostate is when the bladder mucosa is in good condition and the prostate has begun to obstruct the outflow of urine. Delay until the mucosa is greatly injured will mean hazard and likelihood that the injury wil be permanent and beyond repair. When the mucosa of the bladder has begun to suffer it is often because the obstruction by the prostate and the cystitis have reached a degree which soon leads to serious effects upon the kidneys and ureters above. The mere removal of an enlarged and obstructing prostate may be mechanically possible and performed without death, but if a bladder is left behind so badly damaged from chronic cystitis as to render functional restoration impossible and as to leave the symptoms proceeding from the bladder virtually unchanged, then the operation has failed of its ideal success. If the prostate is merely enlarged, obstructs none or very little, and the bladder is in good condition operation is not justifiable. If the bladder is greatly changed from inflammation beyond recovery, and if the catheter may be successfully passed, in most cases office irrigation is preferable and more conservative than operation. Such a bladder is a contraindication to operation.

The Little Mothers' Leagues.—J. Sobel describes the leagues organized among school girls in the tenement-house districts of New York City. The members of the leagues receive lectures and demonstrations on the summer care of babies.

Routine Examination of Milk.—J. A. Roddy suggests

the adoption of simpler methods than now prevail in the routine inspection of a city's milk supply.

Necator Americanus.—R. C. Rosenberger and W. Brinton report the case of a native of Madras, who, although in this country only six years, gave evidence of infestation with *Necator americanus*.

Hospitals for Inebriates.—T. D. Crothers states that the success of the new movement in New York for the establishment of a hospital for inebriates is no experiment or theory. There must be a rare combination of the best methods of the prison, the reformatory, the insane hospital, the sanatorium, and the home, applied with skill and fine discretion. There must be a military plan of responsibility and obligations with rewards and merits, built up and fostered along certain lines that are stimulating and educational.

Overdoing in Tuberculosis.—C. Rayevsky comments on the frequency with which a diagnosis of tuberculosis is made without justification.

Myopia in School Children.—W. H. Bates has found that school children do not focus their eyes accurately on writing on the blackboard, or pictures, maps, persons, or other new or strange distant objects. They become myopic when they do not learn to adjust their eyes properly for distant vision. Myopia is prevented by teaching school children to focus their eyes accurately for distant objects. The Snellen test card is found to be the best object to use for exercises in distant vision. It is placed permanently in each class room where all the pupils can see it from their seats. They are encouraged to read daily the smallest letters they can see, with each eye separately, covering the other eye with the palm of the hand in such a way as to avoid pressure on the eyeball.

Street Virus and Antiformin.—F. Proescher has already reported the discovery of an antiformin-resistant microorganism in the brain of animals infected with street virus. In a recent series of experiments the author has been able to produce hydrophobia by dissolving the brain containing the above microorganism in 20 per cent. antiformin solution and injecting the sediment in animals, thus confirming his original observation.

Placenta Previa: A Warning. J. F. Baldwin.
A Modification of Sluder's Method of Tonsillectomy. L. C. Rood.
Chalk Paste. A Substitute for Bismuth Paste. J. R. Mitchell.
Comparative Value of Some Urethral and Other Germicides. J. B. Clark and L. A. Wylie.
Hints for Radiographers. M. A. Walker.

Viscosity of the Blood.—R. Burton-Opitz states that experiments show unmistakably that the blood-flow changes in harmony with the viscosity and, while the latter may play a very important part under certain conditions, too much clinical importance has been attached to it. It is only when special dynamic conditions exist that it becomes important; ordinarily the effect of the viscous resistance is readily neutralized and it is only when the vasomotor nervous mechanism is rendered more or less sluggish by disease or otherwise that the changes are not equalized and overcome.

Perpendicular Pelvis.—F. H. Martin states that the perpendicular pelvis is one of the peculiarities of skeletal defects noted by him in a previous paper and continued observation has only strengthened his belief in its importance as pointing to coincidental visceral and muscular irregularities.

Venous Retinal Pulse.—M. Black calls attention to the blanching of the retinal vessels caused by pressure on the eye-ball, together with production of the venous pulse, as an index to the general blood-pressure.

Rectal Prolapse.—By L. L. McArthur. See MEDICAL RECORD, July 8, 1911, page 99.

Woody Phlegmon of the Neck.—C. A. Powers reports three cases of this condition and states that the theory of Reclus that it is a form of anatomical reaction of the tissues to the presence of pathogenic organisms or fungi may at this time be accepted in place of a more definite explanation. The general tendency of the disease is toward recovery.

Brain Tumor.—S. Voorhees reports nine cases of this condition, noting some of the earliest symptoms, such as temporary amaurosis, deafness in one ear, loss of sense of direction, etc.

Subhyaloid and Vitreous Hemorrhages.—H. Woods reports five cases that have come under his observation. He finds from the consideration of the whole evidence collected that many individuals recover after having been totally blind from this cause, without the eyes showing evidence of the cause of the condition after recovery.

Esophageal Dilator and Esophageal Sound.—W. Lerche describes these two instruments which he has recently devised.

Intravenous Injection.—J. J. Watson describes his method of fixation of a vein by means of a medium-sized sewing needle passed through the skin and upper quadrant of the vein at right angles to its axis. The hollow needle is then introduced into the vein, while the latter is being lifted by means of the transfixing needle with a hemostat attached.

Rupture of Vena Cava.—E. E. Sherrard and C. A. Smalley report a case of spontaneous rupture of the vena cava within the pericardium.

Tuberculosis in the Southwest.—E. S. Bullock and LeR. S. Peters discuss the advantages of climatic treatment, especially of altitude.

Bronchoscopy.—E. Mayer reports three unusual bronchoscopic cases: one of them, a case of papillomatous growth at the bifurcation of the trachea, completely relieved by removal; the other two, of narrowing of the trachea by diphtheritic stenosis and scleroma.

Placenta Previa—A Warning.—J. F. Baldwin refers to the possibility of concealed hemorrhage going on after the leg has been brought down by the Braxton-Hicks method.

Tonsillectomy.—L. C. Rood describes his modification of Sluder's operation; namely, the use of the ordinary tonsil snare, passed over the tonsil external to the already applied guillotine.

Chalk Paste.—J. R. Mitchell recommends the use of this as a substitute for Beck's bismuth paste.

Urethral Germicides.—J. B. Clark and L. A. Wylie report the results of their experiments, which would indicate that the germicidal power of silver nitrate is not exceeded by that of other silver preparations.

Hints for Radiographers.—M. A. Walker suggests, when a second radiograph of the same part is required, that it can be made on the same plate by the use of a lead screen covering half the plate at a time and making the second exposure on the previously unused plate. This is more economical and convenient than using separate plates.

Cardiovascular Degeneration. J. M. Bruce.
On the Differential Diagnosis of Over-Distension of the Lung and Pneumothorax. H. Walsham.
The Permanence of the Cure of Syphilis by 606. J. McIntosh and P. Fildes.
Acute Dilatation of the Stomach. An Account of Six Addditional Cases, and a Consideration of the Cause of the Coexisting Duodenal Obstruction. C. R. Box and C. Wallace.
On the Occurrence of General Subcutaneous Nonrenal Edema as a Familial Affection. F. H. Edgeworth.
Sarcoma of the Penis. H. M. Galt.
A Case of Anterior Dislocation of the Semilunar Carpal Bone. W. R. Bristow.
A Case of Plus-Pressure Anesthesia for Exploratory Thoracotomy. F. H. Wallace.
Infarct of the Transverse Colon. H. T. Gillett.
Cases of (1) Chronic Pancreatitis, and (2) Carcinoma of the Pancreas. G. Y. Thomson.
Feeding Experiments in Fowl Spirochetosis. A. Balfour.
A Fatal Case of Phlegmonous Inflammation of the Duodenum Following Impaction of a Fish Bone. G. Taylor.

Cardiovascular Degeneration.—J. M. Bruce describes the manner in which intellectual and emotional stresses wear out the cardiovascular system. Between the thirty-third and fifty-fifth years of life women fall victims to disease of the cerebral arteries in greater proportion than men. In cardiovascular degeneration the physical signs are of more individual value diagnostically than the symptoms. A diastolic aortic murmur in this condition should lead one to suspect syphilis, while the presence of a mitral murmur indicates metabolic or gouty disease, in which it is relatively common. Enlargement of the heart without murmur of any kind, but with feeble cardiac sounds and a thickened radial, should make one inquire after physical strain. The management of the case consists in retaining the control one has gained of the cause of the disease, and in resisting as long as possible the growing dangers for which one must be prepared.

Over-Distension of the Lung and Pneumothorax.—H. Walsham states that these conditions can be differentiated from each other by the fact that in *x*-ray examination in the latter the shadow of the collapsed lung can always be seen while in the former it is never so seen.

Salvarsan.—J. McIntosh and P. Fildes state that the intravenous injections, so far as is known at the present time, have fulfilled all that has been claimed for this form of treatment. They appear to be very admirably suited to the treatment of syphilis. Forms of application other than the intravenous are relatively unsuitable.

Acute Dilatation of the Stomach.—C. R. Box and C. Wallace report a series of cases to support their contention that the pressure exerted on the duodenum by the dilated stomach is an important factor in the production of obstructive symptoms. The compression must of necessity be greater before the abdominal cavity is opened, owing to the resistance and counter-pressure exercised by the abdominal muscles. For this reason experiments on the cadaver with the stomach exposed only reproduce in an imperfect manner the conditions present during life. Beyond reiterating the importance of combining lavage with the prone position, the authors state that they have nothing to add as regards treatment.

Nonrenal Edema as a Familial Affection.—F. H. Edgeworth records his observation of six children born to healthy parents who developed a subcutaneous edema at ages varying from 1 to 15 weeks. In one case it was slight and confined to the face, and the child recovered; in the other five death ensued after a period of from 1 to 16 weeks. In three, at least, of the cases no albumin was present in the urine. In the two cases examined post mortem no evidence of nephritis was found. If the possibility of inborn variations in the permeability of capillary walls, and in their liability to damage by circulating poisons, were admitted, it would afford an explanation of those cases of general dropsy of the fetus where no anatomical defects in the placenta and fetal organs are present, of the cases of hereditary trophedema (Milroy's disease), of the susceptibility of certain individuals to erythemata and urticaria on the slightest toxemia, as well as of the history of the children whose cases the author reports.

Sarcoma of the Penis.—H. M. Galt, in reporting a case of the condition, states his belief that it is not as rare as present statistics appear to indicate.

Anterior Dislocation of the Semilunar Carpal Bone.—W. R. Bristow, in reporting a case of this condition, notes that the dislocation of a single carpal bone is a somewhat rare occurrence. Codman and Chase have collected 12 cases of dislocation of the semilunar bone, and in almost all of these cases there has been fracture of the scaphoid as well. In the only two cases in which this dislocation occurred, and in which the scaphoid was intact, the radius or ulna was fractured. In the present case, although a series of photographs and stereoscopic views were taken, there was no sign of fracture of the scaphoid or of the radius or ulna.

Plus-Pressure Anesthesia.—F. H. Wallace describes his apparatus as used for this purpose in a case of exploratory thoracotomy.

Infarct of Transverse Colon.—H. T. Gillett reports a case of this condition and states that two types of cases have been described by Kussmaul and Gerhardt: 1. Sudden abdominal pain followed by nausea or vomiting and also diarrhea, which is at first mucous and watery and at last bloody. Gerhardt states that the blood is bright red when the inferior mesenteric is obstructed, but that in obstruction of the superior vessel it is darker. Kemp states that it is generally dark. In the present case it was bright red in the actions on the third day of the illness. 2. The second type of case simulates acute intestinal obstruction, with distended painful abdomen and sometimes feculent vomiting. The mortality is very high, 92 per cent., in Jackson's, Porter's, and Quimby's cases. Death occurs within three days as a rule; the longer duration, six days in this case, may have been because the colon was affected and the obstruction was not complete.

Chronic Pancreatitis and Carcinoma of the Pancreas.—G. Y. Thomson reports three cases of the former and three of the latter condition and notes the following points: 1. The results of cholecystenterostomy in cases of chronic interstitial pancreatitis compressing the bile-duct are excellent; 2, the difficulty of diagnosis between the two conditions even when a laparotomy is performed, and hence the advisability of cholecystenterostomy in doubtful cases; 3, the mortality in cases of carcinoma, though temporary relief may be afforded by operation.

Fowl Spirochetosis.—A. Balfour concludes from his experiments that spirochetal infection in fowls can take place per os.

Phlegmonous Inflammation of Duodenum.—G. Taylor and C. E. Lakin report a case which had a twofold interest in that, first, the duodenum is an uncommon site for the penetration of a fish bone; and, secondly, in that the condition produced by the latter—phlegmonous duodenitis—is a very rare condition whatever be its cause. In MacCallum's collected series of cases of phlegmonous enteritis many showed absolutely no sign of any breach of the mucous membrane, whereby the organism could have gained access, but, inasmuch as certain of the cases have followed traumatism, he suggests that the injury may have produced a point of lowered resistance into which organisms are carried by the blood stream, and he comments upon the relative freedom from bacteria of the uppermost part of the alimentary tube. In most of the cases of phlegmonous enteritis recorded streptococci have been obtained, and in one case in addition a *Staphylococcus albus* was also found. In the present case the colon bacillus was the organism isolated in pure culture, and this suggests that the infection came from within the bowel; and the fact that the patient had had so-called "bilious attacks" before suggests that the duodenum was

not sterile. The presence of the fish bone *in situ*, however, seems to prove conclusively that in this case the infection came from inside the duodenum and was not blood-borne.

Some Latter-Day Intrusions of the Surgeon on the Abdomen. C. P. Childe.
Primary Sarcoma of the Vermiform Appendix. G. Wright.
The Importance of Drainage in Septic Conditions of the Uterus. J. T. Maclachlan.
Adenopapilloma of the Rectum. R. Parker.
Surgical Interference in Cancer. (An Experimental Study.) A Paine and G. W. Nicholson.
On the Influence of Calcareous Drinking Water in Health and Disease. P. G. Lewis.
Congenital Deficiency of Speech Areas. (Congenital Aphasia.) A. E. Tait.

Surgery of the Abdomen.—C. P. Childe states that surgery, being the simpler science, has naturally outstripped medicine in the treatment of disease generally, and in the present stage of the evolution of the science of healing the treatment of the abdomen is almost exclusively surgical. All must recognize, however, that, at best, surgery, notwithstanding all its modern refinements of technique, is a somewhat crude method of treating disease; and there are not wanting signs that many abdominal diseases, especially those of microbic origin, may in the not distant future revert to the province of the physician and be cured by methods less drastic and more scientific than the knife; and it is probably not a vain prophecy that future generations of medical men, with their hypodermic syringes in their pockets, will marvel at the barbarous methods that have been employed of treating abdominal disease early in the twentieth century.

Primary Sarcoma of the Appendix.—G. Wright notes that, although cases of primary malignant disease of the vermiform appendix have been recorded frequently of recent years, the great majority are examples of carcinoma. Harte, writing in 1908, collected 120 cases, 114 being carcinomata and only 6 sarcomata. The author has been able to find records of two other cases, which, with his own, bring the total up to 9.

Uterine Drainage.—J. T. Maclachlan advocates in cases of postpartum sepsis in which there is a purulent discharge from the uterus the insertion into the latter of a glass drainage tube, which is to be kept there until the discharge ceases.

Adenopapilloma of the Rectum.—R. Parker reports a case of this condition. The growth when removed measured 2 by 3¾ inches.

Surgical Interference in Cancer.—A. Paine and G. W. Nicholson, as the result of their experimental investigation carried out on mice, conclude that incomplete removal of a carcinoma is often followed by a rapid recurrence of greater virulence than that of the original tumor, and that this increase in the virulence is mainly due to the remaining fragments having a very rich blood supply.

Influence of Calcareous Drinking Water.—P. G. Lewis states that there is no evidence that hard water has any bad effect in health or disease.

Congenital Deficiency of Speech Areas.—A. E. Tait notes that congenital cases must be due (1) to lesions—intrauterine or at time of birth—or (2) developmental defects. One or more of the speech areas subsequently to be trained for speech are destroyed or defective. "Congenital deficiency of speech areas" would be a clearer description of the condition, since aphasia carries with it the association of more or less established function of the speech areas, and some subsequent thrombosis embolism, tumor, hemorrhage, meningitis, etc. Congenital cases appear more likely to be bilateral and developmental in origin.

Münchener medizinische Wochenschrift.

July 11 *and* 18, 1911.

Trypsin Treatment of Surgical Tuberculosis.—Brandes writes at length on this subject and covers what has been done in the past as well as his own exhaustive studies at Kiel. He entertains favorable expectations of the method in conservative surgery and cautions against expecting too much from a simple enzyme treatment. The liquefaction is always remarkable, typical in fact. Trypsin is inferior to iodoform-glycerine in bone tuberculosis. Iodoform poisoning often shows the rapidity of the action. It must be remembered that iodoform-glycerine is a resource of very great efficacy, one which is not readily surpassed. Bätzner, one of the first sponsors of the treatment, has recently announced that he finds some trypsins much superior to others.

Subperiosteal Diaphysis Resection in Acute Suppurative Osteitis of the Fibula.—Sulzer states that his method is indicated for the following reasons: 1. If the general condition is severely compromised, it effects rapid evacuation of the pus and diminishes the danger of sepsis. 2. It serves to delimit diffuse suppuration of the fibula, both in subperiostal detachment and when foci exist in the compact bone or marrow. No technique is given because the operation itself is by no means new, being found in standard works on surgery, and was in fact one of Ollier's brilliant pioneer contributions to bone surgery.

The Trachoma-like Disease of the Newly Born.—Wolfrum covers the evolution of our knowledge of this disease, which has interested alike ophthalmologists, microbiologists, and urologists. His article is mainly retrospective and critical with his own personal experience. In Leipzig sporadic trachoma is by no means a rarity, and it develops in subjects who have neither been abroad nor been in contact with suspects. These trachoma subjects may all have had some disease of the sexual organs. In one instance a servant girl had marked trachoma, and she had been taking care of a nursling who had an affection of the eye. Now that attention is directed to such associations we should make some progress. One such case means much. Unfortunately it was impossible to fill out the details of the case. It is, of course, unknown whether she had the so-called inclusion catarrh of the conjunctiva which is believed to stand in some definite relationship with the gonococcus or a frank blenorrhea neonatorum. It may be imagined that a subject with so-called inclusion catarrh of the urethra simulating gonorrhea affects his own conjunctiva and in time develops a true trachoma. Or a pregnant woman with inclusion catarrh of the vagina infects her newly born child with blenorrhea neonatorum. There is no longer doubt that the latter condition may occur with nothing but inclusions in the pus, just as it occurs with both inclusions and gonococci. It is anatomically impossible for an infant to exhibit a condition like true trachoma in the adult, and the rapidly destructive consequences in the child would also give trachoma no opportunity to develop.

Inversion of the Vermiform Appendix.—Langemak reports a case of isolated and complete inversion of the appendix, one of the rarest of affections. Only 15 have hitherto been placed on record. There is almost always an accompanying invagination. The patient was a boy aged 4, whose symptoms pointed to an acute appendicitis. Laparotomy revealed absence of appendix, but corresponding to the site of the latter a funnel-shaped depression. A certain degree of disinvagination was effected by manipulation, after which ordinary appendectomy was possible. An abscess which had formed beneath Poupart's ligament was evacuated. The termination of the case was successful.

Eye Affections in Acne Rosacea.—Three ophthalmologists have reported cases of this association. Hilbert adds a fourth report and advises an examination of the eyes in every case of rosacea. The eye affection does not apparently conform to any known type, at least no diag-

nosis is given. The symptoms comprised lacrymation, reddened conjunctivæ, ciliary injection; chief of all and most characteristic were the corneal lesions. These were symmetrical. On both sides in the horizontal meridian sprang from the thickened limbus a narrow tuft of fine blood-vessels, which ran inward and downward, diverging like a broom. The pupils were very narrow, the vision 5/5 on both sides. The affection was painful. After peritomy on the inner aspects of both corneæ and instillation of homatropin, the pain and lacrymation subsided, but no further improvement resulted until the skin affection was much improved by a dermatologist.

Anesthesia of the Brachial Plexus for Surgical Operations on the Upper Extremities.—Hirschel has recently used this resource in three cases, securing complete anesthesia of the entire arm. The practice is, of course, by no means new, but heretofore results have not been wholly satisfactory. The author's technique secures better access to the plexus and better avoidance of blood-vessels. Novocain was used in 2 per cent. solution. The first case required operation on the elbow joint for a bullet removal. The second was one of tuberculosis of the same joint, while the third was one of osteomyelitis of the ulna. There were some of the common objections to major anesthetics. The entire technique is too extensive for reproduction.

Deutsche medizinische Wochenschrift.

July 13 and 20, 1911.

Diagnostic Significance of Urinary Pepsin in Gastric Diseases.—Scholz states that determination of urinary pepsin might be made useful for recognizing stomach disease as follows: If in clinically doubtful cases of gastric cancer urinary pepsin is present in normal or excessive quantity while the stomach pepsin in a trial meal is devoid of action, and the same result occurs after a bouillon meal, the evidence points to cancer.

Pulmonary Tuberculosis Appearing as a Cardiac Affection.—Rotky refers naturally to the simulation of cardiovascular murmurs by pulmonary murmurs and *vice versa*. A case is given as follows: In May, 1911, a woman aged 55 years was admitted to von Jaksh's clinic who had been in good health until a few months before, when she began to cough violently. It ceased as promptly, after which her legs swelled. She had had climacteric for six years. Uroscopy showed albumin. Respiration 38, chiefly costal. Heart dullness much increased and all valves show murmurs. Pulse 108. Increased arterial tension. Coarse moist râles over lungs, and bronchial breathing over one apex. The woman had beginning cataract and various signs of arteriosclerosis. There were also notable pallor and enlarged supraclavicular and axillary glands. The diagnosis was mitral insufficiency and stenosis, dilated heart, visceral stasis, etc., from cardiac insufficiency, including nephritis. The other symptoms, such as lymphnodes, anemia, etc., suggested metastatic cancer. Nowhere was there evidence of tubercle. Autopsy showed extensive bronchiectasis on both sides, total adhesion pleurisy and enlarged tracheobronchial glands. Tuberculous foci in throat and intestine. There were excentric hypertrophy of the right ventricle and the lesions of heart stasis. Comment is hardly necessary. The individual lesions were recognized, but their significance and correlation wrongly appreciated.

Anaphylactic Intoxication.—Biedl and Kraus state that ox-blood serum, rabbit-blood serum, and Friedberger's anaphylatoxin cause poisonings which differ from anaphylaxis. In these poisonings we miss the bronchospasm caused in guinea-pigs, while the lungs, unlike those of true anaphylaxis, respond to artificial respiration. In dogs, in contrast to the phenomena of anaphylaxis, we see no sinking of blood-pressure while the blood coagulates. There are various other differences in the two kinds of poisoning.

Lefthandedness.—Liepmann concludes a serial on left culture, the final paragraphs of which, as well as the entire article, consider its association with the superiority of one hemisphere and with the function of speech. Naturally a vast amount of different facts have to be collected and analyzed. Ambidexters should be studied, both the natural kind and those who have become so by art or education. Cerebral affections in ambidexters should be studied. The material can naturally be secured from school children. The born lefthanded have not been much studied among the intellectual classes, and the significance of lefthandedness in the mentally defective cannot therefore be fully appreciated.

Use of Salvarsan.—Hoffmann and Jaffe state the drug continues to act as an excellent antisyphilitic and is almost always well borne even in repeated intravenous injections. In very rare instances collapse symptoms appear immediately upon injection. The skin becomes bluish red, the face swollen, there is cardiac weakness, etc., for which it is necessary to inject caffeine and camphor and have oxygen inhaled. These phenomena have never occurred after a first injection. A feeling of heat, with redness of the face, occurring even in the course of the injection is a common prodrome and may enable the operator to cut short the injection. The combined treatment (salvarsan and Hg) is especially recommended for abortive purposes.

X-Ray Treatment of Myoma.—Schmidt states that there are myoma cases and cases of marked menstrual hemorrhage which yield but little or not at all to the *x*-ray. These cases, however, are rare, and due probably to unusual resistance on the part of the ovary (they occur only in young women). There were four deaths in 400 cases, but two were not due directly to the rays. A third death occurred directly after the first series of rays from progressive heart failure; this in spite of the favorable effect on the hemorrhage. A fourth case was of the same type. These cases warn us to keep watch on the heart during *x*-ray treatment, even though it cannot be shown that the rays act directly and deleteriously on the heart.

Treatment of the Thyroid in Thyroidismus with X-Rays.—Simon reports two brilliant results of treating acute "iodine Basedow" with the *x*-rays. The thyroidism had been produced after minimal doses of iodine. The striking and indisputable character of the results lay in the prompt subsidence of the syndrome under the rays. The author recommends the method for acute thyroidism from any cause. It is evident that the rays directly depress the secretion of the glands, so that they may be useful in any condition where the secretory function is in excess, even when there is no acute thyroidism.

Inhalations of Ozone as a Specific Remedy in Whooping-Cough.—A. Varet advocates the use of ozone inhalations for the cure of whooping-cough, and thinks that for the poor hospitals should be established where the children can be kept isolated and given this treatment for whooping-cough. This would at once put an end to the deaths from this disease. The inhalations diminish at once the duration and severity of the paroxysms of cough and vomiting, and soon the child is able to sleep and eat, and regains his strength. The duration of the disease will then be from ten days to a month. The ozone apparatus may be attached to an ordinary current such as is used for an incandescent lamp. The sittings may be from every other day to twice a day, and should last ten to fifteen minutes, with the child 50 cm. from the instrument.—*Revue de Therapeutique Medico-Chirurgicale.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

By THE INSURANCE EDITOR.

METHODS IN EXAMINING.

THE examiner will execute his mission with greater facility and expedition and the quality of his work will redound more to his credit if he cultivates system and method in his examinations. While the examination blanks are framed to assist him in this respect, they must necessarily be compact, and on this account it is impossible to incorporate references to every conceivable contingency. It frequently happens that an important point develops in the case which is only referred to on the application in a general way, or perhaps not mentioned at all, and yet, in order to present a complete report, it is imperative that this point be described fully and in detail. The company must, therefore, rely upon the acuteness and observation of the examiner to ferret out complete information, whether asked for on the examination blank or not, and to give all particulars obtainable. It is not pleasant for an examiner to discover that he did not include certain facts in his report because they were not called for on the blank. The only way for him to cover every point and get a full, rounded report is to invariably follow some definite plan, calculated to accomplish this object with thoroughness and despatch. The following synopsis is one which will aid an examiner, and if this, or a modified form to suit the individual taste or the special blank of the company represented, is observed in every examination, the ground will be well covered, though even then some situation not included in this scheme will come up occasionally. In this skeleton sketch brevity has not been sacrificed for the discussion of details, especially as it is planned to take up each subject referred to later on.

HYGIENIC SURROUNDINGS.—Anything unhealthful or unsanitary in the house or immediate surroundings?

OCCUPATION.—Unhealthful or dangerous? Is it stated correctly in the application?

MORAL HAZARD.—Is the insurance speculative? What is the insurable interest of the beneficiary? Is the amount applied for warranted by the state of finances?

PERSONAL HISTORY.—*Note*—The examiner will not get explicit answers unless his questions are explicit, specific, and insistent, but always with patience and tact. General questions will only bring out generalities and evasions, especially when the applicant is disposed to keep back certain facts or underrate their importance. In order that the information gained from these questions may be complete, it should invariably comprise the name of the disease, number of attacks, the cause, duration, severity and remaining effects of each attack, and the date of the last attack.

Nervous System.—Any dizziness, fainting spells, unconsciousness, convulsions? If so, any suspicion of epilepsy? Also, any insomnia, insanity, apoplexy, paralysis? Any history of headaches, nervous prostration, neuralgia, tremor, sunstroke?

Circulatory System.—Any palpitation, heart trouble, varicose veins, pain in the region of the heart? Dropsy?

Respiratory System.—Chronic or persistent cough or hoarseness, spitting, or coughing of blood? (Always report spitting of blood no matter how trivial or what the alleged source may be.) Any bronchitis, pleurisy, pneumonia, consumption, asthma? Subject to frequent colds?

Digestive System.—Any dyspepsia, indigestion, biliousness? If so, always ask if there was any suspicion of appendicitis, gallstones, or renal colic, and report the answer, whether negative or affirmative. Any hematamesis, appendicitis, intestinal colic, diarrhea, hepatic colic, jaundice, disease of the liver, hemorrhoids, fistula, tape worm?

Genito-urinary System.—Any disease of the kidneys, pelvis of kidney, bladder, prostate, testicles? Any renal colic, dropsy, hematuria, frequent urination, stricture of the urethra, hydrocele?

Unclassified Diseases.—(So called in insurance medicine as a convenience.)

Malarial and Other Fevers.—If malarial, state whether intermittent or remittent. Any hematuria?

Rheumatism.—Articular or muscular? Number of attacks, parts affected in each? Date and duration of each? Heart involved?

Gout.—Very important to report number of attacks, parts affected, severity, and whether any symptoms between attacks.

Syphilis.—Date of initial lesion and secondaries? Any tertiaries? Date of last manifestation and treatment?

Abscess or Ulcer.—Full history. Any suspicion of tuberculosis, malignancy, or syphilis?

Skin.—Syphilis, tuberculosis, or malignancy? If erysipelas, number and dates of attacks?

Nose.—Chronic catarrh? Polypi?

Ear.—Full details of any discharge, whether acute or chronic.

Scrofula, Swelling or Suppuration of the Glands.—Tuberculosis, any suspicion of?

Surgical Operations.—Full details. Any suspicion of malignancy or tuberculosis?

HABITS.—Drugs? More difficult to get history than when alcohol used to excess, also more important.

Alcohol? Amount daily consumed, and the most used in any one day? Ever to excess? If so, frequency, duration of periods, and date of last excess? Ever take any cure? If so, date?

FAMILY HISTORY.—Fill out as required on blank. Give specific causes of death and omit terms such as "Don't know," "Natural causes," "Debility," "Childbirth," and "Change of life" whenever possible. Any tuberculosis in immediate household during past year? If any death from tuberculosis, give date.

PHYSICAL EXAMINATION.—For the physical examination, the applicant's chest and abdomen should be bared. This is easily accomplished by removal of coat, waistcoat, and suspenders, and then rolling up both shirts.

General Appearance.—Healthy or unhealthy? (Do not use the term "Fair.") If pale, state whether due to anemia or ill health, or solely to indoor occupation or natural color. Jaundice, marked sallowness, or evidence of dissipation?

Apparent Age.—As stated or older?

Race.—White or Caucasian? Negro? Indian? Do not answer by giving nationality.

Weight.—Ascertain by scales if near or beyond the limits set forth in table. If excessive, is it due to fat? If light, is applicant wiry or subject to some ailment or recent illness?

Measurements of Chest and Abdomen.—Ascertain by tape on bare skin. If abdominal measurement is excessive, is it due to fat or tumor?

Pulse.—Count before examining, as it may become rapid, intermittent, or irregular merely from excitement.

Arteries.—Thickening or atheroma? High tension? Take blood-pressure if apparatus is at hand. Possibility of aneurysm should not be forgotten.

Heart.—Size, sounds, position normal? Differentiate functional and organic murmurs.

Lungs.—Special attention should be given to apices, as any tuberculosis met with is usually in the initial stage. Note any huskiness of voice and the number of respirations.

Liver and Spleen.—Map out size and location. Any tenderness?

Hernia.—Reducible? Is it supported by proper fitting truss?

Thyroid Gland.—Small goiters often missed. Any exophthalmos or nervous symptoms?

Nervous System.—Test pupillary and patellar reflexes. Any tongue tremor? Is speech normal or hesitating? Are pupils equal in size and are they contracted or dilated? Have applicant walk and observe gait. If any tremor of hands, is it due to organic disease or to nervousness or illiteracy?

Eyes and Ears.—Any impairment of sight or hearing? Ordinary errors of refraction corrected by glasses not worth noticing. If any discharge from ear, is it serous, purulent, bloody, or offensive? Any tophi signifying gout?

Skin.—If any disease, parts affected and extent?

Mouth, Teeth, and Tongue.—Any signs of digestive disturbances, syphilis, or nervous disease?

Deformities.—Curvature of spine? If any, is it lateral of anteroposterior? Give accurate idea of deviation. If hip disease, are there any scars and how much shortening? Describe and give history of any other deformity.

Urine should be passed in clean vessel in presence of examiner.

Women.—All the questions in the blank referring to women should be asked, whether she is single or married. Corsets and all clothing except a thin waist should be removed from chest.

National Insurance Legislation in Germany.—(See pages 331 and 336.)

Some Chronic Diseases of the Lungs in Connection with Longevity, Excluding Tuberculosis.—Arnold Chaplin divides his subject into a consideration of (1) fibroid conditions of the lung; (2) chronic pleural effusions. Cases of fibroid conditions of the lung are often met with and it has been a matter of difficulty to arrive at a satisfactory basis when dealing with them from a life insurance point of view. As to etiology, the greater number of these cases owe their origin to acute pulmonary affections of early childhood. The next important point is the duration of the disease. Some high authorities have held that all fibroid diseases of the lung last a very long time, and are frequently found in old age. Chaplin does not think this is so, but regards from fifteen to twenty years as the average duration of a cirrhosis of the lung beginning in early life. The prognosis of cases beginning late in life is far worse. He sums up by stating that fibroid disease of the lung, unless very limited in extent, is unfavorable from a life insurance standpoint.

With regard to serous pleural effusions, Chaplin does not think that such are necessarily of tuberculous origin. The problem, however, when the exudate has become purulent and an operation has been required is different. The opinion is advanced that the fact that there has been a simple pleural effusion should offer no bar to acceptance by an insurance company, while the same may be said of empyema if occurring in early life, and if the resulting collapse of the lung is trifling; but empyemata taking place after the age of twenty or twenty-five are suitable only with a considerable extra premium and for a short term.—*Transactions of the Life Assurance Medical Officers' Association, London*, 1910.

The Correlation of Diseases; or, What Is Inherited?—G. A. Van Wagenen discusses the uncertainty of everything earthly and states that we live in an atmosphere of probabilities. Not only are we unable to tell when men will die, we cannot even tell what road they will take to the tomb. We turn with hope to the statistics only to recollect that medical statistics are based on uncertain data, family and personal records. Experience crystallizes these uncertainties into opinions and conclusions which we treat as facts. Our loss papers show that men do not die of the diseases we expected them to have and do not inherit the special diseases of their ancestors. What, then, is inherited? The correlation of forces is no longer recognized as a theory and is not limited to physical force. Recent studies seem to have demonstrated that the infinite variety of material objects about us are in essence but different combinations of the electrons and atoms of a single substance or matter. It is not claimed that all diseases are different manifestations of a single essence, but it is suggested that there is one underlying factor common to diseases which appear to be as different as the variations of force and substance. It is further suggested that this factor, which is inherited from our ancestors, and either increased or diminished by environment, is simply the increased or decreased vitality of the ultimate cells which compose our bodies. It is, in fact, weakened vitality, be it inherited or acquired, that renders a person susceptible to infection. In consequence, it behooves the physician to urge treatment of this condition rather than the one or two most troublesome symptoms of the disease. Thus to medical directors of an insurance company the general vitality of a family and the average ages reached, as well as the general character of the deaths, are more important than just what diseases prevailed. Van Wagenen's thirty years' work has convinced him that (1) Consumption and cancer very frequently occur in the same record as inheritance from the same parents. (2) Fistula in ano is frequent in those whose records are cancerous as well as in the tuberculous inheritance. (3) Hernia is frequent in families strongly either consumptive or cancerous. (4) It is very common to find deaths from both paralysis and phthisis associated in the same family record. (5) Bright's disease, paralysis, alcohol or morphine habit, epilepsy, and insanity are frequently an interchangeable inheritance from the same ancestors. (6) Insanity, epilepsy, etc., occur usually in very weak records. (7) Consumptive parents have a large proportion of dissipated children. (8) Both overweight and underweight predispose to diseases of degeneration. (9) It is common to find the parents of a living father or mother reach old age while those of the dead parent died early. (10) The family records of men who have themselves lived to be over seventy are singularly free from all the degenerative diseases either of the lungs, brain, heart, or kidneys. (11) It is also interesting to note how very common it is for an overweight to have at least one parent dead of heart disease, apoplexy, Bright's disease, or arteriosclerosis. Children inherit predisposition to disease in general and not particular disease, or they inherit magnificent vitality which enables them to withstand disease. If this be so it is the duty of the medical director to seek the germ of personal vitality in each case rather than to measure the size and strength of an applicant for insurance or to note what particular diseases his family were the victims of.—*Proceedings of the Twentieth Annual Meeting of the Association of Life Insurance Medical Directors of America.*

Some Medical and Insurance Problems Arising Out of Recent Industrial Legislation.—Sir Thomas Oliver

deals with the recently enacted Workmen's Compensation Act of Great Britain. A somewhat similar law exists in Germany but the organization differs from that of Great Britain in that in Germany there is no claim upon the employer's fund until the injured workman has been in receipt of sick insurance for thirteen weeks, and as the sick funds are largely controlled by the working men themselves they are not likely to allow their fellow-men to remain off work longer than they can help. In Great Britain, on the contrary, an injured workman off work for longer than a week can make a claim upon his employer and be in receipt of both his friendly society pay and his compensation as well. In Holland the law is very similar to that of Great Britain. In France there is a somewhat elaborately designed law of workmen's compensation for injury. The British law has worked well and there has been little litigation between employer and employee. The coal mining boards of directors prefer arbitration to litigation.—*Transactions of the Life Assurance Medical Officers' Association,* London, 1910.

Prevention of Early Consequences of Accidental Injury.—Grunewald says that bad consequences of injuries can be the better prevented the earlier the patient gets medical treatment. With the modern simplification of technique, it is not always necessary to send the patient to a hospital. The most important thing in treating injuries is asepsis. Alcohol disinfection of the hands is sufficient: the hands and forearms are washed for one or two minutes in warm soapsuds, no brush being used; the nails are then cleaned; then 90 per cent. alcohol is rubbed into the skin for five or six minutes. Other authors claim that alcohol alone is sufficient for disinfection. So far as disinfection of the wound and surrounding structures is concerned Grossich's method, consisting of covering the wound and skin with tincture of iodine, has proved quite trustworthy. No previous washing must be attempted, and any necessary shaving must be done dry. Iodine is to be applied to the needle punctures, if any suturing has been done. This method not only puts the physician working on the scene of accident or at the home of the patient on a par with one employing hospital technique, but it prevents any untoward consequences (cellulitis, tetanus, erysipelas) from small injuries.

So far as fractures are concerned, prolonged traction frequently results in weakened limb because of the heavy weights used in the old methods of treatment. Zuppinger has shown that little or no extra weight is necessary if the limbs are placed in such a position as would completely relax the muscles. Instead of complete extension, he uses semiflection, producing it by special apparatus. His methods diminish the time of convalescence. Extension by means of nails driven into fragments (methods of Codivilla and Steinmann) is useful, but is mostly applicable to hospital cases. Grunewald concludes with a plea for more general use of the *x*-rays in injuries of bones and joints, so that small injuries, dislocations, etc., can be more often recognized and untoward consequences prevented. He thinks that some portable *x*-ray apparatus should be widely used in country practice.—*Zeitschrift für Versicherungsmedizin,* May, 1911.

Traumatic Hemorrhage in the Region of the Conus Terminalis.—Hübler details a case of hemorrhage of this nature with a consequent partial disability due to the injury. More interesting, however, is the description of a traumatic neurosis following the disappearance of the consequences of the organic injury. The article must be read in the original, as it is not adapted for abstracting.—*Zeitschrift für Versicherungsmedizin,* May, 1911.

Medical Supervision of Laborers in Germany.—Holtzmann says that the government factory inspectors, who usually have had a technical or chemical training, have charge of the hygienic surroundings of laborers during working hours. In Bavaria, Baden, Würtemberg, and Alsace-Lorraine there are medical men employed in this work; elsewhere they are called in as consultants only. A few firms have private "factory physicians." The law in respect to factory hygiene in Germany is very general in terms, so that inspectors possess much independence in judging individual cases. The following are some of the provisions of the imperial labor law: Employment of children of the school age is forbidden. Children under sixteen years are forbidden to do night work. The employment of white and yellow phosphorus in the arts is forbidden. Female laborers cannot be employed in coke work, in ore mines, salt mines, or in any subterranean works of the same character. Employment of women and children is likewise forbidden in many chemical and other industries where the material used is of special danger to laborers. Holtzmann enumerates the individual industries under this heading. Only necessary labor is allowed on Sundays. For women and children ten hours make the maximum labor day. Special regulations exist in individual German States in reference to dangerous trades, such as lead industry, bristle and brush factories (anthrax!), etc. Raw bristles, etc., must be disinfected by boiling water, steam, or chemical means. Recent vaccination is required of laborers engaged in the feather industry and of those employed in rag-sorting works. Other sections of the labor law detail the minimum provision for ventilation, seating, water-closets, etc.

The German insurance law of 1883 provides for compulsory insurance against illness in the largest industrial branches. Insurance societies (*Kassen*) have been formed, their duty being as follows: (1) They must provide free medical attendance and free medicines, as well as such things as spectacles, trusses, etc. (2) The patient must be paid one-half his wages from the third day of illness on until twenty-six weeks have expired. (3) The same amount is paid to women for six weeks after childbirth. (4) In case of death twenty times the average amount of the daily wage, or at least fifty marks, is given to the family. Furthermore, the *Kassen* may extend voluntarily the above minimum provisions; they may support the patient for one year, instead of twenty-six weeks; may pay as much as two-thirds of the average daily wage; may pay for more expensive dental or orthopedic apparatus; may provide for free board and treatment in a hospital and still pay one-half the daily wage; may extend financial support during convalescence; may provide the services of a midwife and give financial support to pregnant women; may extend support to members of the laborer's family; may increase the amount paid in case of death, and pay money in case of death in the family. Two-thirds of the dues for such industrial insurance are paid by the laborers, one-third is paid by the employers. The laborer's dues must not be higher than 3 per cent. of the daily wage; the actual amount paid differs according to expenses of medical attendance, drugs, etc., in different places; university towns are usually cheapest in this respect.

The author then discusses first aid in case of accidents to laborers. Most factories have prominently placed instructions in first aid: bandages are provided; some industries have a special "ambulance corps" among the laborers; others provide private hospitals; still others keep all the necessary medical supplies for early and subsequent treatment of injured laborers. The author names the minimum requirements in this respect.—*Zeitschrift für Versicherungsmedizin,* January and February, 1911.

Tuberculosis Sanitorium.—The site for the tuberculosis sanatorium to be conducted by the Metropolitan Life Insurance Company in the neighborhood of Saratoga, has been extended to include land lying in the townships of Wilton and Corinth.

Book Reviews.

An Introduction to Dermatology. By Norman Walker, M.D., F.R.C.P.; Physician for Diseases of the Skin, The Royal Infirmary, Edinburgh, Fifth Edition. With 43 colored plates and 79 illustrations in the text. Price, $4.00. New York: William Wood & Co., 1911.

It is twelve years since the first edition of this work appeared, and the issuance of this fifth edition bears ample testimony to the popularity which this work has deservedly enjoyed. The large number of colored plates in addition to the numerous illustrations in the text impart to the volume the character of an atlas of dermatology in addition to its valuable features as a textbook. All of the more common diseases of the skin as well as the rare ones which are met with by the general practitioner are described, while those rare conditions which are of interest only to the specialist are omitted. The introductory section discusses briefly the subjects of structure, classification, diagnosis, and treatment, the last including the modern methods of *x*-ray treatment, phototherapy, and freezing. The following sections deal with the diseases of the skin under these headings: Anomalies of sensation; anomalies of secretion; anomalies of circulation; inflammations (traumatic, neurotic, and infective); new growths; malformations; saprophytes; and anomalies of pigmentation. This volume is replete with the essence of dermatology presented in a form available to the busy practitioner, without the mass of theoretical and controversial detail that fills the pages of the larger works. For this reason also it particularly suits the needs of the average student. From the artistic viewpoint this work maintains the high standard which has characterized former editions.

An Introduction to Bacteriological and Enzyme Chemistry. By Gilbert J. Fowler, D.Sc., F.I.C. Lecturer in Bacteriological Chemistry in the Public Health Department, Victoria University of Manchester; Examiner in Biological Chemistry to the Institute of Chemistry of Great Britain and Ireland. Price, $2.10. New York: Longmans, Green & Company; London: Edward Arnold, 1911.

The subject to which this attractive little volume is devoted requires for its adequate discussion incursions into nearly all the provinces of chemistry, and we accordingly find that the author has been obliged to give what is practically a résumé of the chief facts of organic chemistry together with frequent excursions into the fields of physical chemistry and physics. He has been remarkably successful in compressing a great deal of material into compact, but easily intelligible form, and his explanations of such rather difficult conceptions as the relations between optical activity and molecular structure, asymmetry of the carbon atom, and the chemistry of the sugars are models of brevity and clearness. As the book is intended to be of service also to general readers and to those without a complete laboratory training it includes sections on topics such as bacteriological technique which are not sufficiently full to be used as working guides but still are useful in enabling non-medical readers to follow the descriptions of the procedures and methods involved. Some idea of the general scope of the book may be gained from the following excerpts from the table of contents: Some leading conceptions in organic chemistry; the hydrolysis of starch by amylase; the formation of amylase in the living cell, the alcoholic fermentation of grape sugar; the acid fermentation of alcohols and carbohydrates, the fermentation of cellulose and allied bodies; miscellaneous fermentations; outlines of the chemistry of albumins or proteins; fermentation of indigo, tea, coffee, cocoa, and tobacco; bacteriological and enzyme chemistry in relation to agriculture; the chemistry of sewage purification, etc. A well-selected bibliography closes what is an unusually readable and useful work.

Analyse des Harns. Zum Gebrauch für Mediziner, Chemiker und Pharmazeuten, Zugleich Elfte Auflage von Neubauer-Huppert's Lehrbuch. Bearbeitet von A. Ellinger, Königsberg; F. Falk, Wien; L. J. Henderson, Boston; F. N. Schulz, Jena; K. Spiro, Strassburg, i. E.; und W. Wiechowski, Wien. Erste Häfte. Price M. 15. Wiesbaden, C. W. Kreidel, 1910.

The group of Hofmeister's pupils whose names appear on the title page of the present volume have collaborated in producing a new edition of what was originally the well known textbook of Neubauer and Vogel. Huppert prepared the eighth, ninth, and tenth editions, and the present is to be considered as the eleventh, though in so enlarged a form as to be hardly recognizable. The book is henceforth to be in two volumes, each almost as large as the single one of the tenth edition; and only the first has as yet appeared. It covers the description of the urine in general, its physical properties, chemical properties, and the organic and inorganic constituents normally present. The various topics are naturally treated with the utmost fullness, and the work represents the last word on the whole subject of urine and uranalysis.

Vaccine Therapy in General Practice. By George H. Sherman, M.D., Detroit, Mich. Published for the author, 1911.

This little book is written to interest the physician in the use of bacterial vaccines in every-day practice and incidentally to increase the sale of Dr. Sherman's vaccines. The first few chapters deal with the philosophy of vaccine therapy, early personal experiences, vaccines in every-day practice, and the general use of bacterial vaccines. Then follow chapters dealing with the use of vaccines in the different diseased conditions of the body, such as scarlet fever, typhoid fever, erysipelas, broncho and lobar pneumonia, bronchitis, chronic colds, tuberculous infections, rheumatism, infected wounds, and appendicitis. Dr. Sherman is an enthusiast in the treatment of disease with vaccines, and undoubtedly we all would be if we had obtained the results of which he tells. But unfortunately such is not the case. Although much has sometimes been accomplished with bacterial vaccines, most observers have been disappointed with the vaccine treatment as a whole.

Clinical Analytical Methods. By Karl M. Vogel, M.D. Price 20c. New York: Jas. T. Dougherty, 1911.

This pamphlet, which is intended for use on the laboratory table, contains working directions for carrying out the quantitative determinations required in doing metabolism work, data for making volumetric solutions, etc., arranged in convenient form for ready reference.

The Principles of Pathology. By J. George Adami, M.A., M.D., LL.D., F.R.S., Professor of Pathology in McGill University, and Pathologist in Chief to the Royal Victoria Hospital, Montreal; Late Fellow of Jesus College, Cambridge, England; and Albert G. Nichols, M.A., M.D., D.Sc., F.R.S. (Can.), Assistant Professor of Pathology and Lecturer in Medicine in McGill University; Out-patient Physician to the Montreal General Hospital; Assistant Physician and Pathologist to the Western Hospital. Volume II, Systemic Pathology. Second edition, revised and enlarged, with 301 engravings and 15 plates. Philadelphia and New York: Lea and Febiger, 1911.

It is possible to approach the subject of pathology in a number of different ways. It may be developed from the point of view of the student alone in a compact short textbook, without references, and giving only the main facts. Between this and Ziegler's well-known volumes, which contain enormous numbers of references and a great many remarkable illustrations, there lies a somewhat different field, that of full discussion with a moderate number of illustrations, chiefly photographic, and references only to the most important articles on any one subject. This is the aspect chosen by these writers. This second volume on Systemic Pathology offers less opportunity for originality and variety of treatment than did the first volume on General Pathology. It must necessarily be more diffuse because the lesions of each organ or each system must be taken up in turn. In order to remain within reasonable bounds, however, the utmost care must be employed in pruning the text free from every unnecessary word or discussion. Even with such care this volume runs to 1,160 pages, and unfortunately the heavy paper which has been used makes it a truly ponderous work. The changes from the first edition have been very considerable and apply chiefly to the introductory chapters on the disorders of the ductless glands and to that portion devoted to the nervous system. It is interesting to note in the former how fully the subject has been developed in a limited space. The embryology and physiology of the thyroid, parathyroids, and hypophysis are given in brief, and also an abstract of the more recent views on the relation of the presence or absence of the secretion of these glands to tetany, acromegaly, myxedema, etc. Considerable new matter on the chemistry of the urine has been added. No evidence of double authorship is apparent in the text, and it is evident that collaboration has been very complete. The photographs of gross specimens and patients are admirable. Some of the photomicrographs of tissues are good; others are flat and nerveless and should be replaced either by better photographs or by drawings. The volume remains one of the best in English of its type, though its very bulk must prevent its current use by students as a text. It is rather a book to be consulted at leisure.

INEBRIETY: A Clinical Treatise on the Etiology, Symptomology, Neurosis, Psychosis, and Treatment and the Medico-Legal Relations. By T. D. CROTHERS, M.D., Supt. Walnut Lodge Hospital, Hartford, Conn. Editor of the *Journal of Inebriety*, Author of Morphinism, and Narcomania, Drug Habits, and Their Treatment, etc., Recording Secretary of the American Medical Society for the Study of Alcohol and Other Narcotics, Member of the American Medical Association, The British Medical Association, Honorable Member of the British Society for the Study of Inebriety, etc., etc. Price $3.00. Cincinnati, Ohio: Harvey Publishing Company, 1911.

THIS book is a scientific treatise on the etiology, symptomology, and treatment of inebriety as a diseased condition. Dr. Crothers claims that the entire problem of inebriety is one of scientific, curative, and preventive medicine, which the trained physician is most competent to study and understand. The book is divided into thirty-two chapters. Each chapter treats of some particular phase of inebriety. Some small idea of the thoroughness with which the author handles his subject may be gained by looking over part of the table of contents: "General Symptomology and Development," "Periodic Inebriety and Its Symptomology," "Continuous Drinkers," "Inebriety in the Form of Moral Insanity," "General Causes and Favoring Conditions," "Special Causes of Inebriety," "Prognosis of Inebriety," "Delirium Tremens," "General Principles of Treatment," "Home and Office Treatment of Inebriates," "Institutional Treatment of Inebriates," and "Mental Therapeutics and Suggestion in the Treatment of Inebriety."

Dr. Crothers condemns the routine treatment of alcoholism with hypnotics as unscientific and unsafe. He recommends, instead, eliminative and hydrotherapeutic measures, combined with stimulation when needed. The use of hypnotics, in small doses, is reserved for exceptional cases. Particular stress is laid on the importance of making the patient realize the seriousness of alcoholism and the possible dangers to which it may lead. The author insists on the necessity of keeping the patient under continued medical supervision if truly gratifying results are to be attained.

The book is an excellent one and will prove generally valuable as all physicians have to meet this very trying problem.

DIE BEHANDLUNG DER FRAUENKRANKHEITEN. A Textbook for Practitioners. By Dr. J. VEIT, Professor and Director of the Gynecological Clinic of the University of Halle. With 39 illustrations, some in colors. Price, 12 marks. Berlin: S. Karger, 1911.

IN this work the subject of the treatment of the diseases of women is treated in a concise yet very complete manner by one of the best-known gynecologists of Germany. Although the book contains less than 250 pages, the writer has succeeded admirably in presenting a compendium of modern gynecologic practice free from all theoretical discussion, including with good sense only those procedures which have been satisfactorily demonstrated by his own clinical experience. The reaction from the extreme operative standpoint in gynecology has shown itself by the appearance within recent years of a number of excellent textbooks on what might be called the medical treatment of the diseases of women, and Veit's work in part is a worthy exponent of this class. One of its particular virtues lies in the fact that the conservative methods are satisfactorily defined, so that the reader, whether student or practitioner, has clearly presented to him the indications for operation at the proper time. Some of the particular features of interest in this work may profitably be referred to somewhat in detail.

The first portion of the book includes a description of gynecological methods and the technique of operative treatment. The second deals with the specific therapeutic measures demanded by the individual gynecological conditions. The description of the general methods is very satisfactory and complete, although in the discussion on the office treatment of uterine disease one might question the recommendation regarding intrauterine injections and irrigations; notwithstanding the assertion by the author that this is perfectly safe—it probably is not in the hands of the general practitioner, to whom this book is supposed to be addressed. The various operative procedures are briefly discussed, but the descriptions in certain places might be elaborated with advantage. The author favors the median longitudinal incision through the linea alba in celiotomy in preference to the Pfannenstiel incision, which is only recommended in a limited class of cases. One is rather surprised at the paucity of the methods presented for the treatment of perineal lacerations as compared with American textbooks, no mention being made of the Emmett, Lawson-Tait, or other operative procedures often employed. In the treatment of endometritis the uterine application of caustics, such as chloride of zinc, is recommended, and Veit does not advise curettage in any of the cases in which discharge is the principal symptom. In severe cases he claims that the endometrium must be completely destroyed by deep cauterization in order to effect a cure. It is hardly likely that these views will be accepted in this country without restriction. A very satisfactory discussion of the treatment of retroflexio uteri is presented, in which the author advises the Alexander-Adams operation for the uncomplicated cases, and favors ventrofixation for those that are not complicated by adhesions. On reading the description of the latter operation, this is found to be really a kind of suspension, as the round ligaments are brought forward and attached in a similar manner to that advocated by Gilliam. The treatment of pelvic tumors is very completely presented, and the author inclines most favorably to the early and extensive operation for uterine cancer, favoring the abdominal approach to the exclusion of the vaginal route. An interesting chapter deals with the subject of sexual neurasthenia, which cannot be satisfactorily summarized, and must be read to be appreciated. This remark also applies to the section on the treatment of parametritis.

Professor Veit's work constitutes an excellent and timely addition to gynecological textbook literature, and is deserving of general circulation. The book is carefully made up and the illustrations, although not numerous, are nevertheless sufficient for the purpose. The author must be congratulated on the successful manner in which he has met the problem of writing a textbook free from the presentation of confusing methods and ideas.

LES APPLICATIONS PRATIQUES DU LABORATOIRE À LA CLINIQUE. Principes—Techniques—Interpretations des resultats. Par le Dr. E. AGASSE-LAFONT, Ancien chef de clinique de la Faculté de Paris, chef de laboratoire à l'hôpital Saint-Antoine. Préface par M. le professeur G. HAYEM. 254 figures, dont 109 en couleurs; 1 planche hors texte en couleurs. Price, 10 francs. Paris: Vigot Frères, 1911.

DURING the last ten years an interesting development has taken place in the teaching of medicine. The introduction of laboratory methods, especially those which are too complicated for the practitioner to employ himself, has given rise to a very considerable body of teachers and investigators who devote themselves almost wholly to this laboratory diagnostic phase of medicine. In some institutions the matter has gone so far as to warrant the establishment of departments separated from the chair of medicine, for the teaching of so-called clinical diagnosis. Perhaps, however, the more frequent method is still to retain the subject under the general department of medicine. Each arrangement offers certain points of advantage and it seems probable that ultimately a clean cut separation will take place. The clinician is desperately struggling to hold this most fascinating side of medicine as he realizes more and more his therapeutic impotence in the passing of the center of popular interest to that eminently practical field, surgery. In response to demands for textbooks on laboratory diagnosis a number of excellent volumes are on the market, but the French have recently been especially industrious in this regard, ranging from complete treatises of large size on one subject, as for example the blood, down to small compends in which all the diagnostic methods are given in so compressed a form as to be quite useless to any but the beginner. The author has attempted to define his field in the title, showing that only laboratory methods which are of practical use to the clinician are included. A most striking feature is the excellence of the colored prints which are scattered throughout the book in large numbers. The figures of bacteria especially are well designed; the blood pictures also are very accurate in coloration; and the registration in the half tones is unusually good. Rather more stress is laid upon bacteriology than is usual in such texts, and a short chapter on the preservation of tissues is also appended. The rest of the volume follows the conventional ararngement of the subject, chapters being devoted to the blood, urine, sputum, exudates, and transudates. The cytological and bacteriological examination of spinal fluid is unusually well presented. The treatment on the whole is very well balanced, only tried methods are given, and, while certain pieces of standard apparatus, as for example the Fleischl hemoglobinometer, receive no mention, yet satisfactory descriptions of other simpler forms which are employed by the French are included. The student or physician who has not had a special laboratory training will surely find much in this short text which will help him in diagnosis.

Society Reports

BRITISH MEDICAL ASSOCIATION.

79th Annual Meeting, Held at Birmingham, July 25 to 28, 1911.

(Special Report to the MEDICAL RECORD.)

REPRESENTATIVE MEETING.

THE Representative Meeting, at which much business connected with the association is transacted but does not form part of the public proceedings, began on the 21st of July, and a considerable number of members assembled on that date. That, therefore, was the day on which the conference received an official welcome to the city by the Lord Mayor on behalf of the citizens.

On entering His Lordship's attention was called by a whimsical member to the fact that a great deal of gas was coming into the hall. This gave him a hint he did not lose, for in opening his speech he remarked that he hoped the member did not refer to what he was about to say, but only to subsequent speakers whose views might be known. He was pleased to welcome the association to the city which was its home, though it was twenty-one years since the last visit. Great changes had occurred since then. The death rate had fallen almost half, and the public health authorities had accomplished much. Birmingham people knew that no profession did more for the poor and that was no reason why greater demands should be made. They knew the many honorary services conferred and were glad that their association protested against abuse of hospitals and prevented the treatment of school children being thrust upon them. Their city would not be guilty of doing so, but engaged medical men for that work.

Professor Saundby welcomed the members on behalf of the local practitioners. Mr. J. Chamberlain was elected an honorary member of the association in recognition of his services in promoting tropical medicine and the foundation of the university of which he is chancellor.

GENERAL SESSIONS.

Tuesday, July 25—First Day.

On Tuesday, the 25th inst., the public business began by the Lord Mayor of Birmingham opening the annual exhibition, at which 104 stalls were arranged. He referred to the old story about throwing physic to the dogs and said this scene reminded him of Addison's remark that physic was nothing but a substitute for exercise and temperance.

Sir H. BUTLIN in supporting a vote of thanks referred to this and said in London they had a remarkable phenomenon—a Lord Mayor who did not drink and did not smoke. The annals of the city had been searched about a thousand years for another example, but in vain.

In the afternoon there was a large assembly when the annual meeting was formally declared open. Professor Saundby was formally installed as president, the retiring president, Sir H. Butlin, divesting himself of the chain of office and placing it around the neck of his successor. In the evening came the

Presidential Address.—Dr. ROBERT SAUNDBY delivered this before a brilliant gathering, a great number of members appearing in their academic robes. The assemblage took place in the University, at Bournbrook, about three miles outside the city of Birmingham. The address dealt in clear, decisive fashion with various medical matters, but its chief feature was a severe indictment of the system of contract practice which the government proposes to perpetuate and the declaration that if a fight should be forced on the profession they were not unprepared—an assertion which was received with enthusiastic applause. Small clubs in rural districts established by individual practitioners were often beneficial, as the doctor controlled the admission of members and he got a trifling payment when otherwise he would receive nothing. Clubs connected with collieries and other large works were mostly controlled by the management and their relations with the profession were satisfactory. But when friendly, insurance, and other medical aid societies came in and provided attendance they sought to make a profit out of this department. The General Medical Council had investigated the matter by a committee and the report proved great evils to exist. The council forbade the employment of unqualified assistants, which was an improvement, but the workmen's clubs had not increased their payments. The proposal of an enormous increase of the system under the control of friendly societies filled the profession with dismay. The proposal to attend a third of the population on such terms had caused a resistance which deserved the support and sympathy of the public. The only argument for it was cheapness, but if the health of the people was the greatest national asset the efficiency of medical treatment ought not to be tampered with. They were told that as the burden could not be imposed on the general taxpayer it must be put on the medical attendants. It seemed impossible for Parliament to sanction such manifest injustice. The National Deposit Friendly Society had for years conducted its business on the principle of paying the doctor for work done and was not dissatisfied with the result. The new bill was an adaptation of the German law of 1885. What was the effect there? The formation of a medical organization of more than 21,000 members to meet the question. A trade union it was, ready to use trade unionists' plans—a strike if need be. What had succeeded in Germany could be done here. The British Medical Association was founded with other objects, but had been compelled to create a department for defence. It now numbered 24,000. Without them the Insurance Bill must fail. There was no comparison between Germany in 1885 and this country in 1911. The voluntary principle had provided here a system of hospitals and dispensaries. The President pointed out some of the disadvantages that had been experienced in Germany and said it was commonly believed to have been a corrupting influence sapping the honesty and independence of the German people. The testimony of the ex-President of the Imperial Insurance Bureau at Breslau was enough to show this.

The President, after delivering his address, held a reception of visitors from the oversea dominions and dependencies. Then came the presentation of a certificate of honorary membership to Mr. Joseph Chamberlain as a recognition of the great statesman's services towards the advancement of tropical medicine. Mr. Neville Chamberlain appeared to accept the certificate on behalf of his father. Still later a smoking concert was given by the Birmingham District Practitioners' Union.

Wednesday, July 26—Second Day.

On this day the Sectional Proceedings began, and notwithstanding the late hours of the previous day the sixteen sections were opened by 10 o'clock. The "Daily Journal" of the meeting was in circulation—a good sized 8vo pamphlet, this day's issue reaching 100 pages, but several were occupied with a list of expected members. The Council held their meeting at 9.30. Outside the sections the principal incident of the day was the

Address in Medicine.—Dr. BYROM BRAMWELL, in this address, took for his subject "Mistakes"—not, as he explained, to imply that medical practitioners were more prone to errors than members of other professions, but because of the extreme complexity of the problems

they had to deal with and because, too, to solve them correctly was often a matter of life or death for their patients. Men of extensive experience were ready to admit they made mistakes. It could not be otherwise, considering the impossibility of any one completely mastering the whole of modern medical knowledge and remembering, too, the difficulties they often had in eliciting and observing the facts, and the circumstance that too often they had to rely to some extent on the statements of others, which were apt to be inaccurate and sometimes positively misleading. Mistakes due to erroneous deductions and illogical conclusions were very common; so were those caused by overlooking some fact or facts which proved to have great influence. Some of the differences arising in compensation cases were due to the doctors on one side attaching too much, and those on the other side too little value to the patients' statements and complaints. All hospital men, especially those who studied deeply nerve diseases would agree that since the Workmen's Compensation Act, cases in which nervous symptoms developed after injuries or supposed injuries had become more frequent and the duration of illness more prolonged. His experience was that in such cases the patient did not get well or got well with great difficulty as long as a question of compensation was pending. Personally he had no doubt that if the National Insurance Bill became law the same result would follow in many cases of ordinary illness and the attendance demanded by compulsorily insured patients would be found to be very much greater than had been calculated. Some people seemed to think it was very easy to detect malingering. It was not. Those who had experience among them would agree with him that nothing was more difficult. It was a practical question whether some conditions such as neurasthenia and hysteria ought to be admitted to insurance benefits, though their exclusion would certainly entail hardships on some genuine sufferers.

Thursday, July 27—Third Day.

This was an unusually busy day. Of course all the Sections were in full work. Outside them the day opened for many with the breakfast of the National Temperance League and closed with the annual dinner of the Association, at which Professor Saundby took the chair as President. Between these functions came the address in surgery and a special congregation of the university for conferring honorary degrees, followed by an inspection of the five new buildings. The recipients of the degrees were nine in number, and the ceremony had been anticipated with a good deal of interest because one of them was Mr. John Burns, president of the local government board. Of course, as far as he was concerned the occasion had nothing to do with the British Medical Association, but the degree was in recognition of the assistance he had given to the Birmingham authorities in extending the boundary of their city, and his town planning bill was held to be important from the point of view of public health. In presenting him Sir Oliver Lodge said the medical faculty had represented to the Senate that as head of the department concerned with the sanitary administration of the country he had constantly cooperated with the medical profession in their efforts to improve the public health and had given his powerful assistance to those municipalities which were trying to ameliorate the sanitary conditions of the areas under their control.

The vice-chancellor, who conferred the degrees on behalf of the chancellor, Mr. Joseph Chamberlain, who could not be present, cordially shook hands, as customary, with the newly made LL.D. The other gentlemen were already doctors (of medicine) and now had the Hon. LL.D. added; three of them were from abroad, viz.: Drs. Chittenden, Oppenheim, and P. Strassman. The others were Drs. Byrom Bramwell, F. H. Lovell, J. A. Macdonald, R. A. Reeve and Sims Woodhead.

The Address in Surgery was the other function of the middle part of the day. It was delivered by Prof. Jordan Lloyd of the university, senior surgeon to the Queen's Hospital. After thanking the Council for his appointment he referred to the recent decease of one of the greatest surgeons who had raised the fame of the Birmingham school and also to those who at previous meetings in the city had occupied the chair from which he spoke. He then passed in critical review the whole range of modern surgery with the clearness and caution of one who has taken part in its progress for some thirty years or more.

AMERICAN ORTHOPEDIC ASSOCIATION.

Twenty-fifth Annual Meeting Held in Cincinnati, May 15, 16 and 17, 1911.

Standardization in Orthopedic Instruction and Practice.—Dr. Albert H. Freiberg took this as the text of his president's address. He said that orthopedic surgery was the surgery of chronic conditions. For this reason changes for the better or the worse were the more difficult to appreciate. For instance, the great difference in opinion regarding the progress made in the correction of scoliosis was due more to the inequality of results than to variation in methods of mensuration and recording. He was therefore pleading for a recognition and determination of standard methods in both mensuration and treatment, and perhaps also in methods of instruction to patients. It would also be well to look for a plan by which every new method should be granted a careful trial by experienced reliable men. Such a trial should be thorough and should be made, if possible, with the cooperation of the proposer of the innovation. The result of it must then demand attention. This might be accomplished by the establishment of a standing committee, to whom such questions might be referred for a report at a later time. Perhaps another field of usefulness for such a committee would be in giving an expression of opinion as to the ideal preparation of the graduate who expected to specialize.

Results Obtained by the Use of Tuberculin in Joint Tuberculosis.—Dr. George B. Packard of Denver said that in many cases in which there had been discharging sinuses for a long time and in which, from the clinical symptoms, it was evident that there was mixed infection the results were excellent from the use of tuberculin without an autogenous vaccine. Though cultures were not made, it was probable that in these cases the active organism was the staphylococcus. If there was the slightest question as to the diagnosis the Moro or the v. Pirquet test was made, and always found positive. X-ray pictures and microscopic examination of material obtained by curettage confirmed the diagnosis also in a case in which the secondary infection was severe and the reaction marked from tuberculin alone, without an autogenous vaccine. He would not use tuberculin as a routine treatment in all cases of joint tuberculosis. When either children or adults were doing well and there was no evidence of the disease being active or progressive, and when the general condition was satisfactory he would not use it, but when the disease was progressive and painful, in spite of protection and other general measures, he considered tuberculin to be a valuable adjunct to the treatment.

The Use of Tuberculin in Orthopedic Surgery.—Dr. Walteer G. Stern of Cleveland said that the tuberculin reactions were acknowledged to be specific and could be of even greater value in orthopedic differential diagnosis than in medicine, since one was usually dealing with be-

ginning or early tuberculosis. The accuracy of the tuberculin reaction was as great, if not greater, than most biological tests, viz., Wassermann, Widal, etc. In suspected cases the cutaneous and the ophthalmic reactions were performed at one sitting. If both tests agreed the reaction was held to be positive or negative as the case might be. If the tests disagreed then the subcutaneous or the intracutaneous prick reaction was resorted to. Large doses given subcutaneously caused a focal reaction at the seat of the lesion; this focal reaction was dangerous and should not be resorted to unless all other means of diagnosis failed.

Spengler's I. K. Serum in Tuberculosis of the Joints.—Dr. JOHN L. PORTER of Chicago said that our knowledge in regard to calculating the dosage was inadequate. Better results could be obtained when the dosage had been perfected. The giving of but one dose in seven or eight days had been found to be more satisfactory than the more frequent doses. Under the management of the inexperienced the most common and the most detrimental error would be too large a dose. Marked disturbance of the patient's comfort was the best guide for a reduction of the dose. Too great a desire to hasten the cure would usually result disastrously. Contamination must be guarded against. The posterior exterior surface of the forearm while the arm was held in flexion was the most convenient and least painful site for the injection. Children seldom complained of the procedure if the solution was injected slowly. Tincture of digitalis and strophanthus should be administered throughout the entire treatment. Patients with severe or advanced heart lesions should not be treated with I. K. solution until complete compensation had been restored; and then only while in bed and with the greatest of care and careful dosage. Jumping to a tenfold dose was both dangerous and unnecessary, and it was seldom that patients would tolerate this increase. When rapid immunization was desired it was better to begin with a small dose of a higher dilution. Then after an interval of ten days this could be increased up to lysis. A relatively small daily liberation of antitoxic immune substance could be better calculated by the physiological blood force. He believed that I. K. serum had some curative properties and a constitutional effect on patients with tuberculous joints, and that it was worthy of further trial.

Joint Tuberculosis in Children.—Dr. LEONARD W. ELY of Denver stated that the orthopedic surgeon was responsible for part of the confusion that existed as to the treatment of joint tuberculosis. In the past there had been a tendency to dwell too much upon the non-essentials and to magnify our points of difference. Three reasons were given for the confusion, and three main rules of treatment upon which one might unite, based upon clinical experience and upon laboratory study: First, deprivation of function; second, avoidance of secondary infection; third, fresh air and good food. In addition the fact that radical operations were out of place in children's tuberculous joints was emphasized.

Dr. HERBERT H. GALLOWAY of Winnipeg asked what support there was in the experience of the members of the association for the contention that the focal reaction produced by the subcutaneous injection of old tuberculin was dangerous. He felt that it was exceedingly valuable in doubtful cases and had never regretted its use.

Dr. WILLIAM S. BAER of Baltimore said he did not like the use of the Calmette reaction because cases had been reported in which serious damage had been done to the eye by it, and it gave no information that the v. Pirquet did not afford. He used the latter first to see whether there was tuberculosis anywhere in the system and then employed the injection method if the v. Pirquet was positive, in order to get a local reaction.

Dr. JAMES K. YOUNG of Philadelphia remarked that under certain precautions there was no danger in the Calmette test. The eye should not have any disease in it at the time and should subsequently be protected.

Dr. EDWIN W. RYERSON of Chicago stated that the great value of the Calmette and v. Pirquet reactions was when they were negative. In response to Dr. Galloway's question he stated that he had seen a case in which, after the injection of one milligram of old tuberculin, a tuberculous peritonitis had occurred. It resulted in such speedy death that he thought that the injection had been instrumental in producing it.

Dr. SYDNEY M. CONE of Baltimore said that it was true that negative reactions were more valuable than positive. He preferred the v. Pirquet to the others.

Dr. G. G. DAVIS of Philadelphia did not believe in using the Calmette reaction and said that there was no more obstinate affection in childhood than tuberculous inflammation of the eye, and that when an inflammation was started in the eye of a tuberculous child no one knew when it would stop. The v. Pirquet test was absolutely without objection.

Dr. STERN in closing said that the chief objection seemed to be the Calmette reaction. If an old ulcer was lighted up after a Calmette injection nothing more had been obtained than a focal reaction which was not dangerous. He was glad that the combined reaction was coming into general use because the v. Pirquet alone was not accurate except in a negative sense. It should be checked up by the subcutaneous test or the Calmette reaction.

The Treatment of Hip Disease.—Dr. EDWARD H. BRADFORD of Boston said that hip disease practically considered might be regarded as a chronic carious process of the weight-bearing portion of the hip joint. It tended to deform, flexing, adducting, shortening the limb, with destruction of the head, widening of the acetabulum. Thorough treatment should overcome this tendency to distortion and resulting disability. The threatened deformities were most effectively combated by the employment of a traction during the deforming stages of the disease and an important desideratum in the treatment of hip disease was a practical method of the employment of traction.

The Conservative Treatment of Hip Disease: Exhibition of a New Splint.—Dr. JAMES K. YOUNG of Philadelphia stated that the treatment of hip-joint disease should be based upon the pathology as shown by the clinical symptoms confirmed always by the *x*-ray findings and where possible by exploratory puncture. Mechanical treatment to be thorough and efficient should combine absolute fixation of the pelvis and entire lower extremity, including the foot, combined with moderate traction. Reports of the results obtained by this combination treatment were given.

Dr. B. E. MCKENZIE of Toronto thought that Dr. Bradford could have used the Bradford frame to secure fixation and the prevention of deformity. Through its use one might bring down a femur that had risen up into the pelvis. He believed that the greatest force in the treatment of tuberculous bone disease was the proper use of the sun's rays. He had given up the use of a brace for any kind of hip disease except during the period of convalescence.

Dr. CLARENCE L. STARR of Toronto said that in his treatment by means of traction and extension he had encountered the difficulty of atrophy of the bone, and that he would like to know whether Dr. Bradford's apparatus did not produce this, as did plaster of Paris. His experience was that the atrophy was no worse in the patients subjected to treatment in bed than in those that had been allowed to be up and around, and that it disappeared to a great extent subsequently. He also wished

to know whether Dr. Bradford obtained correction of the flexion deformity with that apparatus.

Dr. Bradford thanked Dr. McKenzie for the reference to his frame, which he used in the acuter stages for a short time, but stated that the other method of treatment allowed the child to walk around. The trouble with Dr. Young's apparatus was that the child would not sit down well with it on. Dr. Bradford had given up perineal straps because either the child or the nurse could loosen them. An *x*-ray would show that there was not the amount of traction that there should be and the child could not move the upper part of the body freely. The speaker did not get much atrophy. The muscles, of course, did not develop as well as those of the leg in use; but they did increase somewhat with the splint on. He assured them that they could get as much abduction with his apparatus as they wished.

Dr. Young thought that the splint he had shown emphasized the combination of traction and fixation.

The Treatment of Flexion and Abduction Deformity of the Thigh by Changing the Angle of the Femoral Neck.—Dr. James Archer O'Reilly of St. Louis presented a paper with this title.

Dr. A. J. Steele of St. Louis said that he understood that Dr. O'Reilly exposed the greater trochanter; and then, with a chisel, passed through the trochanter into the leg, removing and reintroducing the chisel a sufficient number of times to produce a concave surface and making a sort of ball-and-socket joint.

Dr. Young remarked that this operation might be a very useful one, and that he would be pleased to try it when occasion offered. He had abandoned the operation of cuneiform osteotomy about the hip, because, unless a large foreign body was interposed ankylosis would occur sooner or later.

Dr. O'Reilly closing said that with this operation there was no break in the continuity of the bone. The two surfaces slipped over each other. In four cases in which he had had a flexion of ninety degrees he could straighten them down to twenty without difficulty. The *x*-ray showed no marked deformity or angle in the trochanter.

Cyst of the Upper End of the Femur, Simulating Hip Disease.—Dr. David Silver of Pittsburg reported the case of a boy, aged 5 years, who presented a limp, limitation of motion and trochanteric thickening, and atrophy of the thigh; a radiogram showed a cyst, with fracture of the inner wall of the neck. At operation a cavity found filled with sterile fluid and with no lining membrane was seen. At a second operation nearly two years later for the return of limp a dense lining membrane was present and examination showed changes characteristic of ostitis fibrosa.

Dr. Henry L. Taylor of Montclair, N. J., had operated on a case of cyst of the base of the back of the femur in which the symptoms were a little obscure, but entirely different from beginning hip disease. The *x*-ray cleared up the diagnosis, showing a spot about the size of a dime, with enlargement of the bone inward over this area. A later observation showed that the cyst was about to perforate. He cut out a piece the size of a nickel, and the boy was perfectly well three years after the operation.

Dr. G. G. Davis remarked that Dr. Silver had described the growth as ostitis fibrosa, but that there was nothing indicative of malignancy in that diagnosis. He had had a case of cyst of the end of the ulna, in which he found a small amount of granulation tissue, which, when submitted to the microscope, showed beautiful myeloid giant cells. Therefore, it could be called a giant-cell sarcoma; yet the amount of new growth was extremely small. It was a question whether these two classes were not simply slight variations of the same kind of growth, those in which there was much proliferation being called myeloid sarcoma, and the others ostitis fibrosa.

Dr. McKenzie reported that he had had a similar case in a woman forty years of age. The cyst contained serous fluid and had no lining membrane. No curetting was done. Two years and a half has elapsed since the operation, and there was no indication of a reappearance.

Dr. Baer thought that the treatment had to be followed out according to the pathology in each particular case. On the whole he wondered whether curettage was better in the long run. When there was any chance that the cyst was epitheliomatous in character amputation should be done, and no attempt made to save the member.

Dr. Alexander R. Colvin of St. Paul, Minn., had had two cases in which cysts not operated upon had practically obliterated themselves.

A Case of Coxa Vara with X-Ray Plates Made Before and After Operation Took Place.—Dr. John Ridlon of Chicago reported that symptoms were present before there was any shortening, and before the *x*-ray picture showed any bone changes. When first seen, the patient was ten years old and a big fat boy, of the female type, with undeveloped sexual organs. If rachitic infantile cases were excluded and only those from the age of ten years to fifteen or sixteen taken, Dr. Ridlon thought that none could be found that by the *x*-ray did not show slipping at the epiphyseal line. These cases occurred in immature individuals, usually fat children, with a retarded sexual development.

Dr. Bernard Bartow of Buffalo, N. Y., had had a case sent to the hospital to be treated for hip-joint lesion. After a week of rest in bed the symptoms cleared up considerably; and in two weeks they had quite disappeared, so far as the dilatation was concerned and some of the restraint of movement. When permitted to walk there was a slight recurrence; but six or eight weeks of rest again made a considerable improvement. The radiograph showed a change in the epiphyseal line indicating that there had been a process extending through the whole line of growing tissue. There was a slight suggestion of a bend at that point. If the patient had gone untreated with continued weight-bearing, the yielding of the neck of the bone at the line of the epiphyseal growing tissue would probably have been more marked.

Dr. Baer had had two cases similar to the one that Dr. Ridlon was speaking of. He saw each four weeks after the separation, and when it had partially reunited. He operated, driving a nail to fix the head onto the neck in a proper position. Both became absolutely well.

Dr. John Prentiss Lord of Omaha had treated a man fifty-two years old, with no history of trauma, who had a duplication of just these conditions. It appeared to be a typical history of coxa vara.

Dr. Joel E. Goldthwait of Boston had seen most of these cases make a comparatively good recovery; even though the anatomical condition was by no means perfect, the function was usually extremely good.

Dr. Cone remarked that Dr. Ridlon's case was particularly useful to him, as he had brought an *x*-ray plate without a diagnosis. The girl was eighteen years of age, and the only thing pointing to coxa vara was the fact that as a child she was rachitic.

Dr. Davis stated that in Madelung's disease there was softening of the lower end of the radius, giving the appearance of subluxation of the wrist. If this could occur in the wrist it was fair to assume that it could also in other parts of the body.

Dr. Stern reported that one of his patients, a fat boy eleven years old, was operated on for fracture of the femur at the neck a year ago. He was discharged from the hospital with a perfect union, and walked on his limb for nine months, when he suddenly took on an enormous increase in weight. Through the callus, at the seat of the fracture, one could see the fibers of bone

separating at the angle; so it was a local softening such as Dr. Ridlon had described.

Dr. Ralph R. Fitch of Rochester, N. Y., stated that a girl of thirteen years was sent to him for hip-joint disease, which she had had four months. On the way to the office she felt something slip, and the *x*-ray showed complete separation. He operated and put the leg up in a prolonged plaster spica. He does not know how long to keep it on.

Dr. Ryerson had operated on three of these cases because the epiphyseal part of the head had slipped underneath. The operative results were good.

Dr. Silver had had an interesting case in a girl of fifteen who presented symptoms of fracture of the neck of the femur. The *x*-ray showed a wearing away of the neck, the head being in the socket, and the trochanter elevated an inch and a half.

Dr. Ridlon, closing, said that the anatomical condition in all these cases was alike. The functional results were reasonably good. He did not know how long to keep these cases in the plaster splint.

Bilateral Congenital Dislocation of the Lower End of the Ulna (Candidate's Thesis).—Dr. S. Fosdick Jones of Denver reported a case in which the patient was a married woman, sixty years of age. Four years ago she noticed a small lump, about the size of a pea, on the inner side of the left arm. The mass got larger and became painful. The growth was removed, and the wound healed by primary union. She was told that the tumor had been found to be a neuroma springing from the sheath of the nerve. The pain continued, and motion at the left elbow became extremely painful. About six months later a plaster cast was applied, which she wore for four months. In 1909 a hard oval mass the size of a lemon was found on the inner side of the arm, an inch and a half above the condyle of the humerus. A diagnosis of sarcoma at the elbow was made, and the left arm was amputated two inches below the surgical neck of the humerus. The patient had an uninterrupted convalescence. The mass proved to be a small round-cell sarcoma.

Dr. Baer reported that he had had a case in which, after removal of a sarcoma, some means were taken to try to get the hand in a straight position. Three inches of the tibia of a dog were grafted into the lower end of the bone, the two operations being done at the same time. He saw the patient two years and a half afterward, and the position had deviated about ten degrees. The *x*-ray showed the engrafted bone of the dog still in place; but, following the operation, there had been a decrease of bone-marrow. She was able to earn her livelihood as a seamstress.

Dr. Jones, closing, said that he had received a letter on the second of May stating that the patient was getting neuralgic pain and was complaining of pain, probably from interthoracic metastasis.

A Report of the Prevalence of Infantile Paralysis in Missouri.—Dr. James Archer O'Reilly of St. Louis reported a pioneer investigation of the prevalence of anterior poliomyelitis in Missouri, giving the new cases for the years 1910 and 1911 and the cases for five years previous to that date. The information was obtained through two sets of circular letters. The replies indicated that the disease was sporadic over the entire State, but that the great majority of the cases were in the northwestern and western portions. The greater number of the patients lived in the country and away from railroads or electric lines. Comparing the cases in 1911 with those in the five years previous to 1910 it was seen that the disease was becoming much more prevalent, and that it amounted to an epidemic in 1910.

Dr. Robert B. Osgood of Boston stated that during the last year Dr. Lucas and he had been making some transmission experiments in regard to poliomyelitis at the Harvard Medical School. They were able to transmit the disease from the tonsils and adenoid tissue of monkeys as late as five months and a half after the attack was over. They also tried to transmit the disease from the nasopharyngeal mucosa of a monkey that had been kept alive by careful nursing, and found the germs present at the end of five and a half months. Later they obtained the tonsils and adenoid tissue removed from a little girl six months and ten days after having had a spastic paralysis from this disease. The preparation from these was injected in various amounts into three monkeys. One of these animals developed typical signs of the disease, accompanied with paralysis. This showed that human adenoid and tonsillar tissue could preserve the virus while no other symptoms of acute disease were present.

Dr. Robert W. Lovett of Boston stated that as soon as the community began to realize the statistics regarding infantile paralysis there would be a panic, and people would be afraid to send their children to the office of an orthopedic surgeon, where such cases were constantly coming and going. Orthopedists had better begin to treat the disease as infectious, so that they might be able to tell these people that they had taken proper precautions.

Dr. O'Reilly, closing, thought that his report showed a little smaller number of cases than probably did occur in Missouri. A number of cases were improperly diagnosed.

The Operative Treatment of Knee Derangement.—Dr. Nathaniel Allison of St. Louis said that some cases that presented the symptoms and signs of internal derangement at the knee showed nothing abnormal when the joint was opened, and that some cases had typical derangements in the knee, but did not present symptoms or signs tallying with any recognized picture. In these cases exploratory arthrotomy was advisable and useful. A careful, clean operative technique, however, was absolutely essential. Conservatism must have been responsible for many old chronic knees, which might have been saved for joint function by simple arthrotomy.

Dr. Cone remarked that in regard to the question of arthrotomy one should be guided a good deal by what was found to be the cause of the trouble at the joint. Different organisms produced different conditions of varying seriousness.

Dr. H. L. Taylor said that most authors claimed that imperfect extension was one of the cardinal signs of a chronic derangement of the semilunar cartilage, and that orthopedists had also been used to looking at tenderness over the semilunar cartilage as a sign of this condition. He had had a patient who had neither, and wished to ask whether cases in children were common, and whether cases with these symptoms were so.

Dr. Galloway said that it was well known that the peritoneum was exceedingly tolerant of infection, and also that the knee-joint would succumb to very slight infection. In opening the knee-joint there was absolutely no margin for accident or carelessness.

Dr. Goldthwait had never seen a case of semilunar derangement in which complete extension was limited and in which it was not possible to relieve the condition by manipulation, unless the anterior third of the cartilage had been turned on itself, so that the section of it lay directly between the condyles.

Dr. Osgood stated that a foreign body in the posterior portion would not be removed by means of an anterior incision unless one cut through the lateral ligaments. In such cases it was better to make a posterior incision.

Dr. Charles F. Painter of Boston said that there was a type of arthritis that was not dependent upon static condition, but was presumably the result of a low-grade infection of some sort. Exploratory arthrotomy should be

resorted to with extreme rarity. This was equally true of exploratory operations of the abdomen.

Dr. Stern said that lately a great many surgeons had been injecting a solution of formaldehyde and glycerin into the knee-joint, with the idea of preventing infection and rendering operations on the knee-joint less dangerous. He had had cases treated in this way in which severe infection had taken place, and did not think that the method rendered these operations less dangerous.

Dr. Bradford stated that a fool could open the abdominal cavity, but not the knee-joint, without disastrous results.

Dr. John J. Nutt, New York City, said that if a patient wearing a brace had apprehension the brace was not fitting properly.

Dr. Davis's experience with the use of formaldehyde and glycerin had been that unless the patient was anesthetized the injection was an exceedingly painful procedure. One might open the knee-joint to remove synovial fringes and fail to obtain motion again. In a great many of these apparently traumatic cases if the joint were opened a condition that he would term rheumatic supervened, and the patient was left with a more or less permanently crippled joint, in spite of the fact that primary union had occurred with no evidence of infection.

Dr. Allison, closing, said that he had meant to convey the impression that with the absolutely necessary careful technique the knee could be opened without any more fear on the part of the surgeon than he would feel in opening the abdomen. As to the comparison between brace treatment and operative treatment for displaced semilunar cartilage, he thought that if the patient could be relieved in three weeks' time by means of operation this was better than the wearing of a brace.

Prognosis in Chronic Arthritis.—Dr. Charles P. Painter stated that there were three types of chronic arthritis: infectious or rheumatoid, atrophic or neurogenous, and hypertrophic. In the first the prognosis was according to infection or ability to determine it; according to the stage at which the case was taken; according to possibilities for carrying out treatment; according to age, sex, etc.; according to possibilities of recurrence. In the second class the prognosis was according to the stages to which the disease had progressed; according to the stamina of the individual; according to the standards of the chronically disabled patient, and according to the likelihood of progressiveness. In the third class the prognosis was according to ultimate disability; according to the possibility of control of progress.

Dr. George R. Elliott of New York City said that the division of these cases into atrophic and hypertrophic seemed to him to have absolutely no basis to stand upon. The two processes went hand in hand in chronic bone disease. Sometimes one process was working and sometimes the other, and sometimes both together. Late studies on the subject had shown that the primary lesion was proliferative and not atrophic in the atrophic form, and that in the so-called hypertrophic type the intial lesion was atrophic. The classification in chronic arthritis, which was a secondary and not a primary condition, was bound to come along etiological lines.

Dr. Painter, closing, said that it had been necessary to have some basis of classification, and that it seemed best to stick to that broad, though perhaps incorrect, classification.

Tendon Transplantation and Silk Ligaments: A Few Practical Points in Technique.—Dr. E. W. Ryerson of Chicago reported that the preparation of the skin by the iodine method had been so entirely satisfactory that he warmly recommended it. If possible the skin incisions should be so placed that the line of suture would not lie directly over the insertion of the silk. Strong braided silk was much better than several strands of finer silk, which tended to cut through. The value of silk ligaments in suspending the foot at a right angle in cases of drop-foot had undoubtedly become firmly established. The method was safer, easier, and far more rational than the excision of a diamond-shaped piece of skin from the front of the joint. Plain corrosive-sublimate silk was apparently free from disadvantages. It seemed advisable to omit drainage entirely. After the cast had been applied a window was cut out over each incision, in order to allow the wound to dry and to facilitate dressing and the removal of the stiches, which should not be removed before the end of two weeks.

The Use of Intraarticular Silk Ligaments for Fixation of Loose Joints in the Residual Paralysis of Anterior Poliomyelitis.—This paper was written by Drs. Bernard Bartow and William Ward Plummer of Buffalo, and read by Dr. Bartow, who said that the intention, by this plan, was to secure closer approximation of the loose articular surfaces, and to limit motion in certain directions, by placing check ligaments within the joint. These excited reactive inflammation, followed by organization of exudates, as a further limiting process. Resistance was thereby supplied to diminish or prevent deflection of the limb from the weight-bearing axis.

The Treatment of Paralytic Outward Rotation of the Foot.—Dr. Gwilym G. Davis of Philadelphia said that in the treatment of infantile paralysis external rotation of the foot was often a troublesome feature. To overcome it the writer suggests in some cases the use of straps or bands passing from the pelvic band to an apparatus fastened to the foot. In other cases it was proposed to make an incision in the region of the greater trochanter, and, while the foot was rotated strongly inward, to sew, with silk sutures, the overlying fascia fast to the posterior edge of the greater trochanter beneath. In cases in which the tensor fascia femoris muscle was not paralyzed this muscle could be loosened and its lower end turned posteriorly and sewn posteriorly on the greater trochanter and upper portion of the shaft of the femur.

The Results of Muscle-Group Isolation in the Treatment of Spastic Paralyses.—Dr. Nathaniel Allison of St. Louis reported, regarding the effect of alcohol on the nerves injected, that experimental evidence indicated that below the point of injection there was degeneration of the nerve. There was no evidence to show that degeneration extended centrally to any appreciable extent from the point of injection. Regeneration started practically at the point of injection and extended peripherally along the course of the old nerve. The percentage of alcohol used must vary with the length of time in which it was desired to induce paralysis. Experience encouraged the belief that, with the careful selection of cases and with a clean and well-executed operation, muscle-group isolation and induced paralysis might be regarded as valuable therapeutic measures.

Dr. Davis stated that on the condyle of the femur or in certain places on the dorsum of the foot, where, in order to pass the drill obliquely, there would be too wide an incision, one could insert the drill and make an oblique hole, and then make another oblique hole in a contrary direction from the other side, meeting the first in the middle.

Dr. Bradford had seen cases in which the alcohol injections had been made as long as eight months previously, the results having been extremely satisfactory. Of course, the injection was only the beginning of the treatment, and the muscle training must come afterward.

Dr. Walter Truslow of Brooklyn said that very mild paralyses could be corrected by careful muscle education. Troubles of greater degree required braces and muscle education, and those of still greater degree required reinforcement in some way by means of silk ligaments, but also the use of braces and muscle education.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF IDAHO.

April 4 and 5, 1911.

ANATOMY.

1. Give the origin, insertion, and nerve-supply of the biceps flexor cubiti.
2. Describe the abdominal aorta and name its branches.
3. Locate the great sciatic nerve; give its divisions. What muscles does it supply?
4. Describe the shoulder joint.
5. Describe the spermatic cord.

HISTOLOGY.

1. Distinguish and give one location of each of the different muscular tissues.
2. Describe an Haversian system.
3. Describe blood.
4. Describe a neuron.
5. Describe and differentiate an artery and a vein.

PHYSIOLOGY.

1. Mention four forms of muscle stimuli. What do you mean by the elasticity of muscle?
2. Give the location of the respiratory center. What keeps this center active?
3. What is the function of an efferent or centrifugal nerve? Mention the divisions into which efferent nerves may be divided.
4. What is meant by reflex action? Mention the superficial reflexes, the deep reflexes.
5. What are the functions of the pneumogastric nerve?
6. What veins unite to form the portal vein? Name in exact rotation the vessels through which the blood passes from the time it leaves the portal vein until it reaches the heart.
7. What changes occur in the blood in its passage through the liver?
8. Name the refracting media of the eye and the effect that each has on the rays of light.
9. Define myopia, hypermetropia, and astigmatism. State the cause of each condition.
10. Name five special centers existing in the medulla oblongata.

MATERIA MEDICA AND THERAPEUTICS.

1. What is a Pharmacopœia? From what sources do we obtain the materia medica?
2. What is meant by an official remedy? (a) Give the official names of sweet-flag, black cohosh, mercury, corn silk, dogwood, lady's slipper, bitter apple, poke-root, hoarhound, and boneset.
3. What is salol, cresol? What are their action and uses?
4. What are synergist, analgesic, depilatories, sialagogues? Name an example of each.
5. What is an alkaloid? Name one each obtained from nux vomica, opium, ipecac, colchicum and ergot.
6. Explain the difference, if any, between resins and gum resins.
7. Coca, cacao, coccus. Define each and give the uses or properties of each.
8. Colocynth. Give (*a*) synonym, (*b*) its principal constituent, (*c*) its medical properties, (*d*) the U. S. P. dose.
9. From what plant is opium obtained? (*a*) Explain the method of obtaining it. (*b*) Name and give the medicinal action of its most important active principle; (*c*) also a salt of the latter having a different action.
10. Name two forms of crystals and give an example of each.

CHEMISTRY AND TOXICOLOGY.

1. What is the toxic principle of digitalis, aconite, nux vomica?
2. In what poisoning is alcohol a good antidote?
3. Name a poison for which lime or lime water is an antidote.
4. What antidote would you give in case of poisoning by oxalic acid?
5. What is the effect of an over dose of aconite?
6. Mention ten elements with their symbols.
7. How does the so-called aqua ammoniæ differ from the official spirits of ammonia? Give percentage strength of ammonia gas in each.
8. How do chemical compounds differ from mixtures? Give an example.
9. Mention the ingredients of a Seidlitz powder; what chemical reaction takes place while effervescing?
10. Give the chemical formula of morphine.

DIAGNOSIS.

1. Tabes dorsalis; tabulate the principal points of diagnosis.
2. State the principal diagnostic symptoms of scarlatina, diphtheria, variola, rubeola.
3. Give diagnosis of cirrhosis of the liver, atrophic and hypertrophic.
4. Differentiate chronic diffuse nephritis and chronic interstitial nephritis.
5. What is Cheyne Stokes respiration? Argyll Robertson's pupil? Widal's test? Wasserman's reaction? Koplik's spots?
6. Differentiate psoriasis and eczema squamosum.
7. Make a diagnosis of epidemic cerebrospinal meningitis.
8. Name and describe five pathogenic bacilli. State diagnostic value of each.
9. Differentiate diabetes insipidus from diabetes mellitus.
10. State briefly the principal diagnostic points of tetanus, Addison's disease, exophthalmic goiter, chorea.

PATHOLOGY.

1. Define pathology, pathognomonic, pathogenesis, pathophobia, hyperplasia.
2. In what neoplasms is there an increase of epithelial cells? glandular cells? connective tissues? muscle? nerve tissue?
3. What is nephroma? fibroma? lymphangioma? lipoma? chondroma?
4. Describe the condition in any one valvular heart lesion and the resulting changes.
5. Give changes in the blood in any one blood-disease.
6. Describe the lung changes in lobar pneumonia.
7. Mention the principal lesion in typhoid fever, rubeola, Graves' disease, Jacksonian epilepsy, cretinism.
8. Mention five diseases of unknown pathology.
9. Describe the pathology of hepatic cirrhosis.
10. Give the pathology of arteriosclerosis.

THEORY AND PRACTICE.

1. Give the urinary findings and treatment for chronic interstitial nephritis.
2. Give symptoms and treatment of a mitral insufficiency, briefly.
3. Differentiate renal and hepatic colic.
4. Etiology and symptomatology of locomotor ataxia.
5. Give the medical treatment of appendicitis.
6. Describe the general management of typhoid fever.
7. Give symptoms and treatment of cerebral apoplexy.
8. Give symptoms and treatment of exophthalmic goiter.
9. Give the etiology and symptomatology of lobar pneumonia.
10. Give the symptomatology and treatment of smallpox.

OBSTETRICS.

1. Describe the female pelvis, and name the organs contained therein.
2. (*a*) Describe the mechanical movements of the fœtus in vertex presentations; (*b*) in face presentations.
3. (*a*) Are face presentations safely delivered by the unaided efforts of nature; (*b*) under what conditions is early interference indicated?
4. What is the effect of premature rupture of the membranes?
5. Give differential diagnosis of extrauterine pregnancy.
6. Name the various causes of prolonged labor and outline the general treatment.
7. Describe the uterine changes that take place in utero-gestation.
8. What are the dangers of protracted labor to mother and child?
9. (*a*) Name causes of hydrocephalus; (*b*) what is the frequency of its occurrence?
10. What is subinvolution and how may you guard against the condition?

GYNECOLOGY.

1. Describe the clitoris.
2. Describe in full the mucous membrane of the body of the uterus.
3. Describe in full the arterial supply of the uterus and ovaries.
4. Describe in full the Fallopian tubes.
5. Describe in full the perineal body. What are its functions?
6. Give the etiology and symptoms of pudendal hematocele. How would you differentiate pudendal hematocele from hernia?

7. Mention the new growths occurring on the vulva. Give the etiology and appearance of condylomata.

8. What is the parovarium? Describe a parovarian cyst.

9. Give the etiology and symptoms of tubercular salpingitis. Upon what points would you base a diagnosis of tubercular salpingitis?

10. From what must you differentiate a large ovarian cyst? Make a differential diagnosis between a large ovarian cyst and a large fibroid tumor of uterus.

SURGERY.

1. Mention five instruments of accuracy used in diagnosing surgical disease.

2. Describe operating-room technique as to: surgeon, instruments, patient.

3. Write one page concerning surgery and the general practitioner.

4. Give treatment of strangulated hernia.

5. Differentiate pyuria of renal origin.

6. Discuss adenoids and adenoid operation.

7. Compound comminuted fracture of tibia with multiple fragments connected by lacerated periosteum, how treat?

8. Resection of rib, indications, technique, after-treatment.

9. Diagnosis and treatment of tuberculous joint, tuberculous anal fistula.

10. Discuss diagnosis and treatment of talipes.

HYGIENE.

1. Discuss the construction of a sanitary dwelling house, where a near substrata of clay could not be avoided.

2. What are the principal differences between soil air and the atmosphere?

3. Give a common plumbing test for sewer gas leakage, and just how to apply it.

4. Upon what must the prophylaxis of typhoid fever be based, and by what possible and even probable means may the bacillus be conveyed?

5. Name six efficient disinfectants which combine cheapness and utility.

6. Discuss the practical daily hygienic management of the sick room and patient in the following diseases: Scarlet fever, diphtheria, typhoid fever, tuberculosis.

7. (*a*) What is meant by the term, active acquired immunity, passive acquired immunity; (*b*) what conditions may influence natural immunity and susceptibility?

8. (*a*) What is the effect of sufficient physical exercise upon the healthy body; (*b*) of excessive continued effort?

9. What are the requirements to be met by underclothing, and the relative values of silk, cotton, wool, and linen used for that purpose?

10. What are the objections to rice as a sole article of food?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF IDAHO.

April 4 and 5, 1911.

ANATOMY.

1. BICEPS FLEXOR CUBITI. *Origin:* Apex of coracoid process and upper margin of glenoid cavity. *Insertion:* Back part of tuberosity of radius. *Nerve supply:* Musculocutaneous.

2. *The abdominal aorta* commences at the aortic opening in the diaphragm, opposite the twelfth dorsal vertebra, and descending to the left of the spinal column terminates on the body of the fourth lumbar vertebra, where it divides into the two common iliac arteries. *Branches:* Celiac axis (gastric, hepatic, and splenic), superior mesenteric, inferior mesenteric, suprarenals, renals, spermatic or ovarian, inferior phrenic, lumbar, and middle sacral.

3. *The great sciatic nerve* passes out of the pelvis through the great sacrosciatic foramen, below the pyriformis muscle: it extends down the back of the thigh, passing between the great trochanter of the femur and the tuberosity of the ischium; at the lower third of the thigh it divides into the internal and external popliteal nerves. It supplies the Biceps, Semitendinosus, Semimembranosus, and Adductor Magnus *muscles.*

4. See Cunningham's "Anatomy" (1909), page 276; or Gray's "Anatomy" (1910), page 301.

5. See Cunningham's "Anatomy" (1909), page 1168; or Gray's "Anatomy" (1910), page 1377.

HISTOLOGY.

1. *Voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. It is found in the Biceps. *Involuntary* muscle is nonstriated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. It is found in the arteries. The great exception is cardiac muscle, which is involuntary and also striated.

2. See Cunningham's "Anatomy" (1909), page 72; or Gray's "Anatomy" (1910), pages 37 and 39.

3. The *physical properties of blood:* Fluid, somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100° F.).

The *constituents of the blood* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.).

The *red* corpuscles are biconcave discs, about 1-3200 of an inch in diameter; they are non-nucleated and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. The *white* blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes; (2) large mononuclear; (3) transitional; (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood.

4. See Cunningham's "Anatomy" (1909), pages 22 and 448; or Gray's "Anatomy" (1910), pages 807 and 811.

5. See Cunningham's "Anatomy" (1909), pages 78 and 782; or Gray's "Anatomy" (1910), pages 575 and 708.

PHYSIOLOGY.

1. *Four forms of muscle stimuli:* Nervous, electrical, thermal, and chemical stimuli.

Elasticity of muscle is that property of muscle whereby it stretches when subjected to the influence of a weight, and then returns more or less perfectly to its original condition when the weight is removed.

2. The respiratory center is situated in the medulla oblongata, on both sides of the posterior aspect of the apex of the calamus scriptorius. The respiratory center is probably automatic; but its activity is excited by: irritation of cutaneous or pulmonary sensory nerves, by the accumulation of carbon dioxide in the blood, by the diminution of oxygen, or by the presence of heat.

3. The function of an efferent or centrifugal nerve is to carry nerve impulses from the center in brain or cord to the periphery. Efferent nerves are: Motor, secretory, vasomotor, inhibitory.

4. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve: (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

The superficial reflexes are: Abdominal, cremasteric, epigastric, gluteal, palmar, plantar, and scapular. *The deep reflexes* are: Ankle clonus, knee jerk, that of the tendo Achillis, elbow jerk, accommodation of the eye, and light or pupillary reflex.

5. *Functions of the pneumogastric nerve:* "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part (3), *vasomotor* influence to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands: (7) *excito-motor* in coughing, vomiting, etc."—(Kirkes' *Physiology.*)

6. The portal vein is formed by the union of the splenic and superior mesenteric, the gastric and pyloric being tributaries. The blood passes from the portal vein through the interlobular veins, the intralobular capillaries, the intralobular veins, the sublobular veins, the hepatic veins, the inferior vena cava, and into the right auricle of the heart.

7. In its passage through the liver the blood loses plasma, proteids, fats, and salts; gains extractives and corpuscles.

8. *The refracting media of the eye* are: Cornea, aqueous humor, crystalline lens, and vitreous humor. "The refraction effected by the cornea is very great, owing to the passage of the light from the air into a comparatively dense medium, and is sufficient of itself to bring parallel rays of light to a focus about 10 mm. behind the retina. This would be the condition in an eye in which the lens was congenitally absent. Perfect vision requires, however, that the convergence of the light shall be great enough to allow the image to fall upon the retina. This is accomplished by the crytalline lens, a body denser than the cornea and possessing a higher refractive power. The biconvex lens focuses both parallel and divergent rays of light. The function of the crystalline lens is, therefore, to focus the rays of light with the formation of an image on the retina." (Brubaker.)

9. *Myopia* is a condition in which the antero-posterior diameter of the eye is abnormally long, and parallel rays are focused in front of the retina.

Hypermetropia is a condition in which the antero-posterior diameter of the eye is abnormally short, and parallel rays are focused behind the retina.

Astigmatism is a condition in which, owing to a greater curvature of the eye in one meridian than in others, the refractive power of the eye varies.

10. *Five special centers in the medulla:* (1) Respiratory, (2) vasomotor, (3) cardiac, (4) for mastication, (5) for deglutition.

MATERIA MEDICA AND THERAPEUTICS.

1. A *pharmacopœia* is a work containing: (1) directions for the preparation, etc., of medicines and (2) a list of accepted drugs and (3) established standards of strength and purity of the drugs contained therein. *Materia medica* may be obtained from animal, vegetable, mineral, and synthetic sources.

2. An *official remedy* is one recognized by the Pharmacopœia. The official name of sweet-flag is calamus; of black cohosh, is cimicifuga; of mercury, is hydrargyrum; of corn silk, is zea; dogwood *is not official;* lady's slipper is cypripedium; bitter apple is colocynth; poke-root is phytolacca; hoarhound is marrubium; boneset is eupatorium.

3. SALOL is phenyl salicylate; the salicylic ester of phenyl. *Physiological action:* Antiseptic, germicidal, anodyne, and antipyretic; it combines in most respects the actions of phenol and salicylic acid.

Therapeutic uses: As a disinfectant, in inflammation of the mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera.

CRESOL is a mixture of cresols obtained from coal tar, but freed from phenol, hydrocarbons, and water. It is a germicide and antiseptic.

4. *Synergist* is an agent which aids the action of another; example, the prescribing of two or more purgatives at one time. *Analgesic* is an agent which causes freedom from pain; as opium. *Depilatory* is an agent which will remove hair; as electricity. *Sialagogue* is an agent which promotes the flow of saliva; as pilocarpus.

5. An *alkaloid* is a basic, nitrogenous substance of alkaline reaction, and capable of acting with an acid to form a salt in the same way that ammonia does. The active principles of some drugs are alkaloids. An alkaloid of nux vomica is strychnine; of opium, is morphine; of ipecac, is cephaëline; of colchicum, is colchicine; of ergot, is cornutine.

6. *Resins* are natural or induced, solid or semi-solid exudations from plants, characterized by being insoluble in water, mostly soluble in alcohol, uncrystallizable, and softening and melting at a moderate heat. Chemically they are mixed products. Some of them are acids, and combine with alkalies, forming soaps, as in the case of common resin. They are commonly the oxidized terpenes of plants. When pure, they are usually transparent, hard, and brittle; when they contain water, are opaque and no longer hard and brittle. They are divided into three classes: (1) *Natural oleoresins* (oil and resin), generally obtained by incising the trunks of trees which contain them; ex., turpentine. (2) *Gum resins:* natural mixtures of gum and resin—usually exudations from plants; ex., myrrh. (3) *Balsams:* resinous substances which contain benzoic, cinnamic, or analogous acids; ex., balsam of tolu. (Stewart's *Pharmacy.*)

7. *Coca* is the dried leaves of the erythroxylon, coca which contains the alkaloid cocaine. It is used as a local anesthetic. *Cacao* (Theobroma cacao) is cocoa, used as a beverage; the oleum theobromatis or cacao-butter is used for suppositories. *Coccus* is cochineal, chiefly used as a coloring agent.

8. COLOCYNTH. *Synonym:* Bitter apple. *Principal constituent:* Colocynthin. *Medical properties:* a bitter, an intestinal and hepatic stimulant, a drastic cathartic, and diuretic. *U. S. P. dose,* 1 gram.

9. Opium is obtained from Papaver somniferum, by incising the unripe capsules. Its most important active principle is morphine, which is narcotic and analgesic. Apomorphine hydrochloride has a decided emetic action.

10. *Two forms of crystals:* (1) Cube, as sodium chloride; (2) right octahedron, as alum.

CHEMISTRY AND TOXICOLOGY.

1. The *toxic principle* of digitalis is digitoxin; of aconite, is aconitine; of nux vomica, is strychnine.

2. Alcohol is a good antidote for carbolic acid.

3 and 4. Lime or lime water is an antidote for oxalic acid or oxalates.

5. An *overdose of aconite* produces muscular weakness, shallow and irregular breathing, cold and clammy skin, lowered body temperature, numbness and tingling of extremities, impaired sensation, and finally paralysis of heart and respiration.

6. Hydrogen, H; oxygen, O; chlorine, Cl; mercury, Hg; arsenic, As; antimony, Sb; carbon, C; potassium, K; sodium, Na; silver, Ag.

7. *Aqua ammoniæ* is an aqueous solution of ammonia containing 10 per cent. of the gas.

Spirit of ammonia is a 10 per cent. solution of the gas in alcohol.

8. *Chemical compounds* are substances containing two or more elements, *chemically united,* and in *definite proportions.*

Mixtures contain elements or compounds in *no definite proportion,* and *without chemical union.*

9. *Scidlitz powder* contains sodium and potassium tartrate, about 120 grains, and sodium bicarbonate, 40 grains, in one paper, and 35 grains of tartaric acid in another paper. The chemical reaction on their mixture is:

$$2NaHCO_3 + KNaC_4H_4O_6 + H_2C_4H_4O_6 + [xH_2O] = [xH_2O] + Na_2C_4H_4O_6 + KNaC_4H_4O_6 + 2H_2O + 2CO_2$$

10. *Chemical formula of morphine:* $C_{17}H_{19}NO_3 + H_2O$.

DIAGNOSIS.

1. See French's "Practice of Medicine" (1910), page 1087; or Osler's "Practice of Medicine" (1909), page 893.

2. See French's "Practice of Medicine" (1910), pages 322, 191, 306, and 330; or Osler's "Practice of Medicine" (1909), pages 132, 200, 115, and 141.

3. See French's "Practice of Medicine" (1910), pages 847 and 850; or Osler's "Practice of Medicine" (1909), pages 560 and 561.

4. See French's "Practice of Medicine" (1910), pages 922 and 930; or Osler's "Practice of Medicine" (1909), pages 693 and 697.

5. *Cheyne-Stokes respiration* is a type of breathing in which the respiration gradually increases in depth up to a certain point, then decreases, then stops for about half a minute; then this cycle begins again.

Argyll-Robertson pupil is the condition in which the pupil reacts to accommodation but not to light.

Widal's test.—See French's "Practice of Medicine" (1910), page 1219.

Koplik's spots are small red spots with a bluish-white center, seen on the mucous membrane of the mouth early in measles, before the skin eruption.

6.

PSORIASIS.	SQUAMOUS ECZEMA.
1. Course chronic.	1. Course acute, subacute, or chronic.
2. Involves with predilection extensor surfaces.	2. Involves with predilection flexor surfaces.
3. Itching moderate or absent.	3. Itching present.
4. Patches sharply defined.	4. Patches fade into healthy skin.
5. Patches small and round.	5. Patches large and irregular.
6. Eruption always dry.	6. History of previous moisture.
7. Patches covered with profuse shining, silvery scales.	7. Patches covered with sparse, small yellowish scales.
8. Lesions remain unchanged from month to month.	8. More or less rapid changes in lesions.

(Schamberg.)

7. See French's "Practice of Medicine" (1910), page 146; or Osler's "Practice of Medicine" (1909), page 163.

8. *Bacillus tuberculosis, Bacillus anthracis, Bacillus ty-*

phosus, Bacillus influenzæ, and *Bacillus lepræ.* See French's "Practice of Medicine" (1910), pages 334, 402, 68, 132, and 409; or Osler's "Practice of Medicine" (1909), pages 285, 252, 59, 153, and 360.

9. See French's "Practice of Medicine" (1910), pages 973 and 978; or Osler's "Practice of Medicine" (1909), pages 419 and 425.

10. See French's "Practice of Medicine" (1910), pages 416, 551, 558, and 1156; or Osler's "Practice of Medicine" (1909), pages 260, 756, 766, and 1048.

PATHOLOGY.

1. *Pathology* is that branch of science which deals with disease (including its causes, manifestations, and results).

Pathognomonic means characteristic of a certain disease.

Pathogenesis is the mode of origin of a disease.

Pathophobia is a morbid fear of disease.

Hyperplasia is a pathological condition in which the cells of a part increase in number and so cause an increase in the size of that part.

2. There is an increase of epithelial cells in carcinoma; of glandular cells in adenoma; of connective tissues in sarcoma; of muscle cells in myoma; of nerve tissue in neuroma.

3. *Nephroma* is a tumor composed of kidney tissue.

Fibroma is a benign tumor composed chiefly of fibrous tissue.

Lymphangioma is a condition characterized by enlargement of lymphatic vessels.

Lipoma is a benign tumor composed of fatty tissue.

Chondroma is a benign tumor composed of cartilage.

4. See French's "Practice of Medicine" (1910), page 587; or Osler's "Practice of Medicine" (1900), page 804.

5. See French's "Practice of Medicine" (1910), page 519; or Osler's "Practice of Medicine" (1909), page 727.

2. See French's "Practice of Medicine" (1910), pages 588 and 608; or Osler's "Practice of Medicine" (1909), pages 805 and 816.

3.

HEPATIC COLIC.	RENAL COLIC.
1. A history of having recovered gallstones from the feces at previous attacks.	1. Possible history of having passed calculi with the urine.
2. Attack begins some hours (two to four) after a full meal.	2. Not influenced by eating.
3. Paroxysmal pain, radiating to the scapula or right shoulder.	3. Pain radiates along the course of the ureter, and patient may feel the site of pain getting lower and lower as the stone passes toward the bladder.
4. Tenderness in the region of the gall-bladder and in the epigastrium at right of the median line.	4. Tenderness may be elicited along the course of the ureter, but is often absent.
5. Chill antedates the pain.	5. Chill less common.
6. Jaundice usually develops within the first twenty-four to forty-eight hours.	6. Absent.
7. Urine bile-stained.	7. May be bloody or contain calculi.
8. Calculi may be passed with the feces.	8. Absent.

2. See Williams' "Obstetrics" (1909), pages 256 and 278; or Hirst's "Obstetrics" (1909), pages 396 and 410.

3. See Williams' "Obstetrics" (1909), page 280; or Hirst's "Obstetrics" (1909), page 414.

4, 6 and 8. See Williams' "Obstetrics" (1909), page 658; or Hirst's "Obstetrics" (1909), pages 570 and 440.

5. The following tables (from Dorland's *Obstetrics*) give the main points to be looked for in a *differential diagnosis of extrauterine pregnancy:*

From *cornual pregnancy:*

EXTRAUTERINE PREGNANCY.	CORNUAL PREGNANCY.
Rupture is most prone to take place at some period during the first three months.	Rupture usually occurs between the third and sixth months.
The tumor exists to one or the other side of the uterus, and is usually distinct.	There may be but one tumor, this being dependent upon the degree of bifurcation.
The tumor is exceedingly sensitive and semi-elastic.	The tumor is not so sensitive and presents the characteristics of a uterine tumor.
The round ligament may be felt attached to the uterus on the inner or uterine side of the gestation sac.	The round ligament is displaced outward and is attached to the external side of the gestation sac.
Examination of the removed specimen shows an absence of true decidual tissue.	True decidual tissue will be found surrounding the fetal membranes.
In interstitial pregnancy the gestation sac communicates with the uterine cavity by the orifice of the Fallopian tube.	The two halves of the uterus are united by a muscular band.

From *pyosalpinx:*

EXTRAUTERINE PREGNANCY.	PYOSALPINX WITH INDISTINCT HISTORY OF PREGNANCY.
The uterus is enlarged, with a soft cervix and the peculiar softening of the body that is present in pregnancy.	The uterus is probably not enlarged, the cervix is not soft, and there is not the elastic feel that is present in pregnancy.
There is a history of sterility, with the signs of endometritis or salpingitis.	There is a history of acute attacks of peritonitis occurring at intervals after an attack of gonorrhea.
The tumor is small, exceedingly sensitive, but, as a rule, not firmly bound down in the pelvic cavity.	The tumor is large, moderately sensitive, firmly bound down in the pelvis, and surrounded by a mass of exuded lymph.
Rupture is likely to occur at some time during the first three months.	The history may have covered a period of months without the symptoms of rupture.
The usual clinical manifestations of pregnancy will be present.	The clinical manifestations of pregnancy are absent or very indistinct.

From *intrauterine pregnancy with fibroid tumor:*

EXTRAUTERINE PREGNANCY (TUBAL VARIETY).	INTRAUTERINE PREGNANCY COMPLICATED WITH FIBROID TUMOR.
There is discovered to one side of the uterus a mass, rounded, exceedingly sensitive, and elastic or semi-fluctuating.	The mass may be rounded; more often it is nodulated, very hard, non-elastic and non-fluctuating, and not sensitive to the touch.
The uterus is enlarged, but not to a size proportionate to the period of gestation.	The size of the uterus corresponds to, or is even in excess of, the time of gestation.
The menstrual history is irregular, and there may be an early return of the show.	Menstruation is likely to be suppressed.
Rupture occurs at the usual time.	No signs of rupture follow.
Pain is an early and prominent symptom.	Pain develops only after the tumor has reached sufficient size to press upon the surrounding structures.

From *lateral flexion of a pregnant uterus:*

EXTRAUTERINE PREGNANCY.	INTRAUTERINE PREGNANCY WITH LATERAL FLEXION OF THE UTERUS.
The body and cervix of the enlarged uterus are generally in a straight vertical line.	The fundus lies to one side of the pelvis, with the cervix carried to the opposite side.
The extrauterine gestation sac is in close proximity to the body of the uterus.	A deep sulcus may be felt between the fundus and the cervix.
Anesthetization reveals the mass closely attached to the fundus and readily outlined.	Anesthetization reveals a normal condition of the appendage.
The size of the uterus is much below that indicated by the duration of the pregnancy.	The size of the uterus corresponds to the period of the gestation.
The menstrual history is irregular.	Menstruation is suppressed.
There is a history of severe abdominal pain and rectal tenesmus.	Usually there is no pain other than a backache; there is no rectal tenesmus.

GYNECOLOGY.

1. See Cunningham's "Anatomy" (1909), page 1197; or Gray's "Anatomy" (1910), page 1420.
2. See Cunningham's "Anatomy" (1909), page 1191; or Gray's "Anatomy" (1910), page 1412.
3. See Cunningham's "Anatomy" (1909), pages 1192 and 1185; or Gray's "Anatomy" (1910), pages 1412 and 1403.
4. See Cunningham's "Anatomy" (1909), page 1185; or Gray's "Anatomy" (1910), page 1403.
5. See Williams' "Obstetrics" (1909), page 247.

Functions of perineal body: It holds in position the lower end of the rectum, vagina, and urethra and enables them to perform the functions of defecation, coitus, parturition, and urination; it strengthens the pelvic floor.

6. *Pudendal hematocele* may be caused by trauma, a fall, varicose veins prior to labor, or pressure of the fetus (particularly of the head).

In pudendal hernia: There is a tumor which is soft, insensitive, and rounded; and which is apt to disappear with a gurgling sound on pressure or if the patient is put in the knee chest position; it is tympanic on percussion, and may give an impulse on coughing. In *pudendal hematocele:* There is generally a history of trauma, no impulse on coughing, no resonance on percussion, and it is not reducible.

7. *New growths occurring on the vulva* are: Lipoma, fibroma, angioma, papilloma, sarcoma, carcinoma. For *condylomata of vulva* see Rose and Carless' "Surgery" (1908), page 149.

8. See Williams' "Obstetrics" (1909), page 47; or Cunningham's "Anatomy" (1909), page 1187; or Gray's "Anatomy" (1910), page 1403. For *parovarian cysts*, see Rose and Carless' "Surgery" (1908), page 1295 and 223.

9. *Tubercular salpingitis* is secondary to tubercular infection elsewhere, generally tuberculosis of the endometrium. *Symptoms:* Mild fever, weakness, thickening of subperitoneal tissues; there is apt to be atresia of the tube and formation of pyosalpinx; it generally attacks both tubes. The *diagnosis* is made on history of tuberculosis and presence of tuberculosis in other organs, finding the tubercle bacilli in the leucorrheal discharge. Generally there are present ascites, scanty menstruation or amenorrhea and the tubercular nodules may be palpated.

10. Large ovarian cysts are to be differentiated from: Ascites, pregnancy, and large uterine tumors.

FIBROID TUMOR.	OVARIAN CYST.
1. Slow growth.	1. Usually more rapid growth.
2. Facial expression unchanged. Face may be full and flushed; later pale from hemorrhage.	2. Facies ovariana.
3. General health usually unimpaired except from loss of blood, if submucous or mural; may be painful.	3. General health early impaired from emaciation. Not painful.
4. Abdomen usually very asymmetrical from irregular shape of tumor.	4. Abdomen more symmetrical, especially when tumor is large.
5. Abdominal veins not usually enlarged.	5. Usually enlarged, especially in large polycysts.
6. Usual menorrhagia.	6. Menstruation unchanged or diminished.
7. Elasticity, not fluctuation. No percussion wave.	7. Fluctuation marked, Percussion wave marked.
8. Surface firm and usually lobulated.	8. Surface yielding; in monocysts, regular; in polycysts, irregular.
9. Vaginal touch and conjoined examination show tumor dense and firm, and, unless pedunculated, continuous with uterus. Uterus large and heavy.	9. Uterus normal, except displacement from pressure. Tumor compressible, fluctuating, detached from uterus.
10. Uterine cavity much elongated.	10. Not materially elongated. (This is a most important diagnostic point.)
11. Uterus moves with tumor.	11. Does not move with tumor.

SURGERY.

1. Microscope, steel tape measure, hematocytometer, cystoscope, *x*-rays.
2. See Rose and Carless' "Surgery" (1908), pages 268, etc.; or Da Costa's "Surgery" (1908), pages 57, etc.
4. See Rose and Carless' "Surgery" (1908), page 1103; or Da Costa's "Surgery" (1908), page 995.
5. In pyuria of renal origin the pus will be found very thoroughly mixed with the urine; whereas if the pus comes from the urethra it will be chiefly found in the first part of the urine voided; and if it comes from the bladder it will be chiefly found in the last part of the urine, and at the end of micturition.
6. See Rose and Carless' "Surgery" (1908), page 835.
7. See Rose and Carless' "Surgery" (1908), page 482; or Da Costa's "Surgery" (1908), page 464.
8. See Rose and Carless' "Surgery" (1908), page 928; or Da Costa's "Surgery" (1908), page 632.
9. See Rose and Carless' "Surgery" (1908), pages 655, 657, and 1134; or Da Costa's "Surgery" (1908), pages 550 and 1009.
10. See Rose and Carless' "Surgery" (1908), page 454; or Da Costa's "Surgery" (1908), page 662.

HYGIENE.

1. "Perfect dryness of foundation, walls, and roof, and exclusion of ground-air, are necessary conditions of house construction. The subsoil around the site, and, if there is much damp, also below it, should be drained, and, except where there is a rock foundation, the walls should be embedded in concrete, and under the whole house should be a layer of concrete 6 inches thick, having on the top a layer 1 inch thick of some impervious material, such as asphalt or cement. In order to prevent damp rising from the ground a *damp-proof course* should be inserted in the wall just above the ground level. Perforated slabs of glazed stoneware may be made to serve not only as a damp-proof course, but to ventilate the space under the floor. It is advisable to have a damp-proof course also where the rain-gutter joins the parapet, and in chimney-stacks just above the roof. Basement walls are liable to become wet when in contact with a damp soil even when there are drains and damp-proof courses. In this case 'a dry area' must be formed by digging out or by building a second thin wall outside and a few inches away from the main wall, or by

inserting slabs in a slanting position between the soil and the house wall, or the walls may be built hollow (with two damp courses) and joined together with iron ties or bonding bricks, or the hollow may be filled with asphalt. Walls exposed to driving rain or sea spray may be coated with slates, vitrified slabs, alkaline silicates, or cement; but such coating should continue down to the 'footings,' and should not be applied while the bricks are wet. The walls of a newly-built house are damp from the water used in mixing the mortar, and also that absorbed by the bricks. If salt-water, sea-sand, or refuse lime from soap works, containing glycerine, has been used in the mortar, it will never dry. Mortar should be composed of good lime combined with clean sharp sand, free from earthy matter (road scrapings or mold have sometimes been used by unscrupulous builders), or with crushed stone, slag, or well-burnt clay. Walls are sometimes built of concrete made with cement. For internal walls, where space is limited, coke-breeze with cement has been used. The settling of the walls sometimes breaks the drain passing underneath, if not properly protected by concrete or by the formation of an arched opening in the wall. It is usual to defer putting in drains until after the building has been carried up, with the view of allowing it to settle upon its foundations. If there be no cellars the flooring ought to be raised two feet above the ground, which should be covered with cement and the space ventilated to prevent growth of the fungus of 'dry-rot.' Walls and ceilings are usually covered with plaster, which should be of good materials ('jerry' builders have been known to use a mixture of lime and sifted mold or street refuse for this purpose). It should be finished with a smooth, non-porous surface. If a room is not to be papered the walls should be coated with some form of cement or distemper. (*Aids to Sanitary Science.*)

2. Soil air contains much the same ingredients as atmospheric air, but in the former there are more carbon dioxide and less oxygen; soil air also contains products of fermentation and decomposition (marsh gas, ammonium sulphide, sulphuretted hydrogen, etc.).

3. The *"smoke test"* consists in filling the system of plumbing with smoke, which will escape if a leak exists.

4. See French's "Practice of Medicine" (1910), page 107.

5. Steam under pressure, boiling water, quicklime, corrosive sublimate, formaldehyde, and tricresol.

6. See French's "Practice of Medicine" (1910), pages 324, 194, 109 and 397; or Osler's "Practice of Medicine" (1909), pages 138, 207, 99, and 353.

7. (*a*) *Immunity* is a state, natural or acquired, in which the body is resistant to disease. *Acquired* immunity is obtained by an individual in consequence of having suffered an attack of a pathogenic organism of normal or modified virulence, or of its toxin, and having overcome it (*active immunity*), or as a result of the injection of the serum of an animal which has acquired an active immunity against the organism in question (*passive immunity*). (From Stedman's *Medical Dictionary.*)

(*b*) See French's "Practice of Medicine" (1910), page 60.

8. (*a*) *Effect of Sufficient Physical Exercise.*—"(1) Increased force and frequency of the heart's action, and by consequence the increased circulation of the blood through all parts of the body. (2) The pulmonary circulation being quickened, more carbonic acid and moisture are eliminated. The amount of air inspired and expired is largely increased. (3) The action of the skin is heightened, and perspiration becomes marked. (4) The water and salts of the urine are decreased owing to the large cutaneous secretion, but the nitrogen eliminated remains about the same. (5) The voluntary muscles are brought into active play; the circulation of the blood through them is accelerated; waste products are rapidly carried away for excretion; while the material to replace waste is brought to them." (Parkes' *Hygiene.*)

(*b*) *Excessive continued effort may cause:* Overstrained heart; breathlessness, palpitation; small, frequent, and irregular pulse; cardiac pain; dilatation or hypertrophy of the heart rupture of blood-vessels; diseases of blood-vessels.

9. *Requirements of underclothing*: (1) To preserve the body temperature: (2) to allow evaporation from the skin to take place readily; (3) to protect the body from heat, cold, rain, and wind; (4) to allow muscular freedom; (5) to disguise the body as little as possible.

Silk is a good non-conductor of heat, is hygroscopic, and pleasing to wear, but is expensive. *Cotton* is cheap, durable, much less hygroscopic than wool or silk, is warm. *Wool* conducts heat badly, absorbs moisture readily and gives it off slowly, but it hardens and shrinks on washing. *Linen* is much like cotton, but more expensive; it is useful in hot climates, and for articles that need frequent washing.

10. Rice is too poor in proteids, fat, and mineral matters.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the weeks ended July 29 and August 5, 1911:

Blood Pressure in Childhood.—W. Koupe studied this subject and found that in 144 normal children the blood pressure varied between 80 and 100. There is no marked difference in the blood pressure of the sexes. The blood pressure appears to rise after the seventh to the eighth year. The difference between the systolic and diastolic blood pressure is quite constant, and amounts to 8 to 9 mm.—*Monatschrift für Kinderheilkunde.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended August 5, 1911:

CHOLERA.

A MEANS OF CONTROLLING THE HEMORRHAGE FROM INOPERABLE NEOPLASMS OF THE BLADDER; WITH CASES ILLUSTRATING THE TRYPSIN AND HODENPYL SERUM THERAPY.*

BY L. BOLTON BANGS, M.D.,

NEW YORK.

THE chief source of misery to a patient with an inoperable neoplasm of the bladder is the recurring hemorrhage. It not only weakens him but it terrifies him and causes a psychic aggravation of the frequent and painful urination. Even before the acts of urination become painful he has learned to study the character of the urine, to estimate its blood contents, and to watch the shades of color with daily intensified interest, trying thus to determine the progress of his malady. If blood clots appear in the urine his agitation increases. He may pretend indifference, but it is perfectly evident what is upon his mind, and that he dreads to ask the question, "Have I cancer?" At this juncture, if the hemorrhage can be controlled or diminished and tactful explanations made, the patient's excitement will be averted and his happiness be restored for a time.

What local remedy is to be used? It should be one which the bladder will tolerate. For, if the mucous membrane be irritated the frequency of urination will be increased, while as each time that the bladder contracts it expresses from its neoplastic contents more blood the patient's sufferings will be aggravated. The application must not cauterize, lest sloughs should separate and cause copious bleeding, or by their irritating presence induce violent vesical tenesmus. It should, if possible, penetrate the substance of the tumor and constringe its soft tissues, and it must preserve as long as possible the sterility of the urine. In trying to find a remedy to meet these requirements various substances were tested, such as solutions of the vegetable and metallic astringents, including Squibb's compound alum powder, adrenalin, antipyrine, and creolin. Creolin, in my opinion, comes nearer to the ideal than any other subsance, but it has its limitations and there is an art in its use which must be acquired. It is a distillate from coal tar and was highly recommended by von Esmarch as an antiseptic with hemostatic properties.

Having had an opportunity of testing its properties in serious hemorrhage from a tuberculous ulcer in the urethra, and finding the statements of von Esmarch to be substantiated, it occurred to me to use creolin in suitable bladder cases. My experience with it in such cases has demonstrated its usefulness and has strengthened my confidence in it. Take in illustration the following cases, only the salient features of which, for brevity's sake, are given. The first was that of a man aged seventy-six, who came complaining of irritability of the bladder and of blood in his urine. His urine was rusty in color and contained many clots and the evidences of chronic nephritis were present. He was much agitated and his countenance showed great anxiety. Cystoscopic examination showed on the lower right segment of the bladder a sessile tumor of about the size of a plum, reddish in color, and with a cauliflower-like contour. Blood could be seen oozing from the depressions on its irregular surface. The bladder wall contiguous to and surrounding the tumor was intensely hyperemic. Its appearance and the symptoms warranted a diagnosis of epithelioma. The patient had marked arteriosclerosis with cardiac valvular lesions and was the subject of suffocative attacks, sometimes accompanied by a sense of impending death. With this history, together with the character of the tumor, it seemed unwise to subject one of his age to the risk of an operation, and in my opinion the best possible proccdure was to control the hemorrhage and to try to keep him comfortable.

The simple boric acid irrigation of the bladder used at first relieved the irritability somewhat, but aggravated the hemorrhage. Consequently I tried the experiment of using creolin, at first in a 1 per cent. solution; but this was soon found to be painful and irritating and was reduced to one of one-quarter of 1 per cent., which was tolerated and found to be efficient. Careful experiment showed that a prolonged application of the weaker solution was better than attempting the use of one which was immediately expelled. Subsequently, however, the patient's bladder became more tolerant, and a strength of one-half of 1 per cent. was frequently used. After 2 ounces of the creolin solution were introduced into the bladder the patient was kept quietly supine, and the solution was retained from twenty to thirty minutes. A gradual lengthening of the time of retention took place until he could retain it indefinitely. I then increased the temperature of the solution from 100° F. until 104° F. or 105° F. and even higher was tolerated, and apparently was more effective than the lower temperature. This was done in order to add the constringing effect of heat to that of the creolin. The patient received these treatments every day, at first an occasional intermission being made to note the result. After the fourth day there was no visible blood. It recurred on the sixth day, when treatment was resumed and repeated every second or third day thereafter for thirty-three days, when

*Read at a meeting of the Practitioners' Society of New York, February 3, 1911.

examination with the cystoscope was again made. The tumor had diminished in size, but its irregular contour remained, and blood issued from its surface. The hemorrhagic area which surrounded it had entirely disappeared, so that the small and delicate shadow which the tumor cast on the posterior wall of the bladder a little to the left of the right ureter was distinctly visible. Treatment with creolin was continued on each third or fourth day, and a little over three weeks (twenty-five days) later the patient was again cystoscoped. Again the tumor was seen to be reduced in size. It was cone-like, harder and firmer in appearance, and looked like a strawberry with its apex uppermost. There was no bleeding from its surface. The treatment was repeated every three or four days and two weeks later the cystoscope was again used. The tumor was still smaller and its color had changed from a reddish hue to yellowish white, while the mucous membrane of the bladder surrounding its site had become a glistening bluish white. For another period of three weeks the treatment was given each third day, when the patient was again examined with the cystoscope. There was no reduction in the size of the tumor, but its surface was firm and solid. The cotyledon-like depressions of the original growth were shallow and closer together and there was not the slightest appearance of blood-vessels in it. But a large vessel, tortuous and pulsating, could be seen leading along the posterior and the midwall of the bladder into the base of the tumor. Four more treatments at three-day intervals were given, after which the patient left for his home in a distant State (South Carolina). There was no blood in his urine, there was no irritability of his bladder, and with the exception of his cardiac attacks he was in good condition for a man of his age.

About a year and a half later he came again with a few small blood clots in the urine, which was otherwise clear. Cystoscopy showed the tumor to be of the same size as at the last record and covered with firm-looking yellowish-white epithelium. At one edge of it was a tiny bleeding point. The applications of hot creolin solution were made on five occasions, when the bleeding ceased entirely and he returned to his home. Two years and four months later he came for inspection. He was feeble, but there was no blood in his urine, either macroscopically or microscopically, and considering his age and cardiac infirmity he was in very comfortable condition. Five months later, in his eightieth year, he suddenly died from what was reported to me as "Bright's disease." Doubtless he succumbed to his cardiac lesions.

It will be observed that for a period of about four years this old man was kept comfortable, free from serious hemorrhage, and that for the last two years and over of his life there was no bleeding whatever. In view of all the conditions this case may be said to be brilliant and justifies the claim made for creolin. Doubtless the good result was aided by the facts that the patient had an unusually tolerant bladder, a resolute and philosophical temper, and was amenable to the measures used for his benefit. No other equally successful case has come under my observation, yet those which follow have interesting features and illustrate the usefulness of creolin. Take for example the case of a man aged fifty-six, who came saying that for eight or nine years he had had blood in his urine, but that sometimes he would go several months without passing any blood. There had been no pain or frequency of urination, but he thought that urination was easier when blood was present. Recently, however, a change had taken place; there was a constant desire to urinate, say every fifteen minutes, together with a sensation of scalding with each act. This frequency and pain, rather than the hemorrhage, led him to seek advice. The urine voided in my presence was claret-colored, and at the end he forced out a large clot. The creolin treatment was begun immediately. In twenty-four hours there was relief to the irritating and constant desire to urinate, but the urine was tinged with blood, which was of a dark color. The solutions were given daily for two weeks, their temperature being raised to 105° F., which caused some irritation of the bladder. Meantime a small fragment of tissue was found in the midst of a blood clot. This was sent to a laboratory, which reported that it had all the characteristics of papilloma, containing large epithelial cells like those of the bladder, infiltrated with leucocytes, and tissue cells in an advanced stage of fatty degeneration. Other fragments obtained from time to time were submitted to the laboratory, which reported that the cells were such as were seen in teased specimens of carcinoma or epithelioma. The treatment was continued off and on for several months, when, bleeding and irritability having ceased, the patient disappeared. I did not see him again for a period of about seven and a half years. He stated that three times in this long interval he had had a little blood in his urine which ceased spontaneously. At this time he was urinating every three hours in the day and not at all at night; but the urine was claret-colored. I tried antipyrine and adrenalin, but without effect. Then the hot creolin solutions were resumed and the bleeding ceased in three days. Again he dropped out of sight. One year and four months later he reappeared and submitted to cystoscopy. This revealed an egg-shaped tumor the size of a robbin's egg in the wall of the bladder, more to the right of the midline than to the left, and just above the right ureteral orifice, which was seen as a dimple beneath it. The outline of the tumor was regular and the surface roughened, its color pale and bloodless. There was a small reddened area on the left upper aspect of the tumor. The patient had had no blood in the urine since his last visit over a year ago. He was to report again in three months for further examination, but I did not see him until two years later, when he came stating that blood had appeared in his urine five or six times during the last six months. The hot creolin solutions were repeated once a week and the bleeding ceased promptly. But as it reappeared from time to time I insisted that he should go into hospital for more radical treatment. The patient was now more docile and consented. The bladder was opened suprapubically, and such diffused masses of epithelioma were found that removal was impossible. The wound united promptly, with the exception of a narrow sinus which had to be assisted by a few applications of silver nitrate. The blood in the urine was lessened but not stopped by the creolin applications and injections of trypsin were begun. These were made subcutaneously in the wall of the abdomen, but he complained of great pain at the time and of considerable pain following each injection. Notwithstanding these complaints the trypsin injections were given daily for over a month, *i.e.*, thirty-two

days. Instillations into the bladder of lotio pancreatis were substituted for the creolin, in the hope of obtaining some specific action upon the neoplasm. These did not control the bleeding nor have any other beneficial effect. A mawkish odor of the urine was noticed and the latter became muddy and reddish brown, with several clots. The hypodermatic injections of trypsin and the instillations of lotio pancreatis were carried out with fair regularity every other day for over two months without staying the progress of his malady, and after weakening slowly he died.

In the early stages of the history of this patient he was utterly unmanageable. He was very corpulent (with a wheezy voice), short of stature, and timid and apprehensive. An employee in one of the city departments, he was in constant dread lest he should lose his employment. Moreover, it was his conviction that the bleeding which had come at intervals during the eight or nine years prior to his coming to me and during his lapses of treatment had ceased spontaneously, and, therefore, he had convinced himself that treatment was not necessary. As a result of this state of mind he was fitful in his attendance and came at long intervals until toward the end of his malady. During his first visits to me, while blood in the urine and irritability of the bladder persisted, he was tolerably faithful and came nearly every day till relief was obtained. He then disappeared and was not seen for seven and a half years. It will be noted that in this interval he had blood in his urine only three times, but as this hemorrhage ceased spontaneously he did not come for treatment. Again, as soon as the bleeding and irritability were controlled he dropped out of sight and did not reappear until over a year later. At this time it was possible to make the cystoscopic examination already noted. After another interval (of two years) he stated that his urine had contained blood every five or six weeks during the last six months. Creolin solutions of one-half of 1 per cent. promptly reducing the amount of blood, he remained self-confident, but three months later he was alarmed about himself and consented to the operation, which was then too late.

In further illustration of the use of creolin and also as an example of the use of the Hodenpyl serum, take the following history of a male, aged sixty-eight, who first came directly under my care November 23, 1909. In February, 1908, he had experienced frequent and scalding urination with blood in his urine. His then attending physician, being an expert, had cystoscoped him under general anesthesia and found a large neoplasm occupying the base of the bladder and involving the right ureter. A year and a half later, his surgical attendant being out of practice for an indefinite time, he came under my care. The patient had been bleeding steadily every day for the previous six months, occasionally voiding very large clots, some of them so large as to obstruct urination until bladder tenesmus forced out the clot. He was weak and despondent, his countenance was anxious, and he looked exsanguinated. Although confined to his room, he insisted upon getting out of bed and being clothed every day, but the slightest effort caused dyspnea. The amount of blood which he passed was very large and the coagulation on the bottom of the vessel in which the urine had been saved was ⅛ to ¼ inch thick. Creolin solution, one-half of 1 per cent. was used and retained only twenty minutes daily from December 15 to December 27, when it was recorded, "the solution is retained half an hour, there are no clots and much less blood in the urine; patient's general condition improving." Two weeks later, January 11, 1910, the urine was macroscopically free from blood, and he held it for two and a half hours. His anxious gray look had disappeared and he was strong enough to go downstairs. I then cystoscoped him in the attempt to determine whether or not more radical measures should be used. The operation was done under chloroform anesthesia. It showed an irregular, soft tumor with a cauliflower-like appearance springing from the right side of the base of the bladder and covering approximately two-thirds of the right lateral wall of the viscus. In view of the patient's condition and of the size and distribution of the mass it was decided not to operate further, but to continue the creolin and to test the Hodenpyl serum, if this could be done without arousing the patient's suspicion as to the nature of his malady. The patient's strength had increased to such a degree and the bleeding from the tumor was so well controlled that he was able to go for a daily drive and at a moment when he was cheerful and hopeful he was told that injections of serum were to be given him in order to improve the state of his blood. This satisfied the patient and he contentedly agreed to the procedure. Dr. Hodenpyl held that injections of the ascitic serum under the skin or into the veins cause necrotization of cancer structure, and that the injections do no harm nor cause any secondary toxemia, but that moderate doses repeated for a long time were safer than large doses, because the latter cause such rapid disintegration of the neoplasm that the blood-vessels do not have time to contract and that dangerous, even fatal, hemorrhage may ensue. This had been his experience in external or visible tumors, and, therefore, his advice in regard to a tumor in which the changes were not visible was to use moderate doses subcutaneously (not intravenously) for a period of several months, even after the local malady had disappeared (I quote Dr. Hodenpyl's words).

Beginning on January 28 an injection of 50 c.c. of the ascitic serum into the subcutaneous tissues of the abdomen was made daily. No local or general reaction followed, but three days later, namely, on January 31, some change had evidently taken place. The residual urine, which had varied from one-half ounce to one and a half ounces, had increased to two and one-half ounces. There was great frequency of bloody micturition and so much difficulty in expelling the urine that a permanent indwelling catheter with siphon drainage was installed. Constant attention to the tube was required, as vesical tenesmus forced clots by the side of the catheter, and the drainage was interrupted by the clots.

February 1 the instillations of creolin solution were resumed and given twice daily. Six drams of the one-fourth of 1 per cent. strength were retained forty minutes. To rest the urethra the permanent catheter was removed at the end of twenty-four hours, but reintroduced on the following day, when the patient passed a comfortable day, with very little hemorrhage and only a few spasms. A week later, February 7, the record shows good nights, and very little blood in the urine. The patient went on in this way until the 17th, that is for ten days, being fairly comfortable, but with

occasional attacks of difficulty in voiding his urine, apparently due to an increase of the obstacle to the outflow. The catheter was used at intervals in order to relieve the urgency and to remove the residual urine, which seemed to be increasing in quantity. It was now necessary to introduce a greater length of the catheter before getting the residual urine, which had increased to four ounces, whereas formerly it was one or two ounces at the most. The increase in the length of the urethra and of the amount of the residual urine would seem to bear out Dr. Hodenpyl's statement that the first effect of the serum injection is an increase in the volume of the tumor, a sort of swelling which in the case of external tumors is distinctly visible. February 22 further change was taking place in the obstruction. The patient was able to void only two to four drams of urine at a time and the residual that day was five ounces. The catheter was, therefore, used more frequently and occasionally left in for a few hours in order to rest the patient by keeping the bladder empty. On February 24 there were frequent attacks of tenesmus, forcing out a bloody deposit, granular in nature, not at all like broken-down clots. The eye of the catheter was frequently clogged with blood clots and sloughing tissue. The latter caused frequent spasms, which were relieved by flushing the bladder with boric acid about every forty minutes.

Thirty days after beginning the serum decided difficulty was found in passing the catheter, which also had to be entered more deeply, the length of the urethra being now 12½ inches, whereas formerly it was but ten. The sensation given to the hand of the operator using the catheter is that the obstruction is of a rigid or firm nature in strong contrast to the soft or yielding feeling originally noted. Apparently a marked increase has taken place in the size of the tumor, for a few days later the urethral length was 13½ inches, the sense of obstruction just mentioned was intensified, and stiff, gum-elastic catheters became necessary. Dr. Hodenpyl inferred from this increased length of the urethra that the first effect of the serum, viz., an increase in the size of the neoplasm, had been obtained, and that disintegration with consequent contraction of the tumor might be expected.

The serum injections of 60 c.c. were given daily for fifty days, when it was noted that the patient had less scalding, and on the whole had improved very much. But although he voided more urine each time the interval remained from forty-five minutes to one hour. The creolin solution was continued on every reappearance of blood, and now apparently some retrogression of the tumor seemed to be taking place, for there was less difficulty in introducing the catheter, and no holding on withdrawing it. The catheter at 10½ inches now withdrew one-half ounce of residual urine, and at 13½ inches one-half ounce more. On the fifth day thereafter the catheter at 10½ inches withdrew three ounces of residual urine. The patient's general condition was also improved and he went out daily for a drive. For a period of fifteen days (from April 18 to May 3) there was so little blood in the urine that the creolin was omitted, but an accession of blood again required its use, with the usual result.

On May 25 the patient left for his home in the country in relatively good condition. His urinary intervals were from one to two hours and very little blood was passed. The creolin was to be used only when there was an accession of blood. Sometimes it was necessary to do this twice, and even three or four times in the twenty-four hours. The patient continued in about the same condition, creolin treatment being used whenever the blood appeared to be increasing in quantity. The urinary intervals varied from forty-five minutes to one and a half hours, scalding during the act being more or less present all the time. It was occasionally necessary to resort to suppositories of morphia in order to relieve the excessive irritability of the bladder. The serum, 50 c.c., was administered with daily regularity without any constitutional reaction that we could note. The general strength of the patient was maintained until the early part of August, when there was evidence of failure of strength. The amount of blood in the urine was controlled by the creolin, but the frequency of urination, accompanied each time by much scalding, increased to every fifteen or twenty minutes, with an hour's interval occasionally. The bladder became so irritable that it was impossible to use a permanent catheter, and I considered, with his attending physician, the question of making suprapubic drainage; but in view of the patient's extreme debility, and from the fact that he could be kept comfortable with morphia, this was thought inadvisable. Up to about the middle of August, when the supply of ascitic serum gave out, the injections of 50 c.c. had been given with daily regularity. It seemed to me, therefore, that the treatment thus faithfully tested had caused no betterment of the symptoms. Early in September the patient suddenly became uremic and died in coma. No autopsy was permitted.

The following case not only emphasizes the hemostatic value of the creolin solution, but strikingly illustrates the insidious way in which a neoplasm may develop while its presence in the bladder is unsuspected by the patient.

A man aged seventy-eight was placed under my care on February 22, 1910, by his family physician, Dr. Kinnicutt, to be treated for the involuntary escape of a few drops of urine. The patient stated that he had had this symptom for some months and at first had paid no attention to it, but lately the frequency and urgency of urination had increased so that he was compelled to urinate every hour. The urgency is now so sudden that it is impossible for him to reach the closet before the urine escapes. He gives no history of blood in his urine at any time, and he is not aware that the urine contains blood microscopically. Subsequent examination of the bladder and prostate reveals moderate enlargement of the latter and that he has one ounce of residual urine which is hazy and contains blood. The catheter when withdrawn is decidedly blood stained. After the examination free blood present in the urine made it evident that a more definite diagnosis must be made. Cystoscopy revealed a tumor of about the size of a butternut springing from the posterior margin of the prostate and from the contiguous portion of the base of the bladder. Its surface is irregular, it is bluish red in color, with a cauliflower appearance, and portions of it are covered with clotted blood. The creolin treatment was begun at once, and in two days the blood was controlled so that there was no free blood in the urine and no clots, but the microscope revealed the presence of blood discs. Scalding at every act of urination was now very pronounced. The Hodenpyl serum was now given by his family physician, but the old gentleman complained greatly of the pain,

so that only a small dose was administered, and this not daily. A second cystoscopic examination a month later confirmed the previous examination as to the location and size of the tumor, but the latter was now being covered with a grayish white pellicle similar in appearance to that reported in the first case in this paper. He complained bitterly of the serum punctures. At the end of the first week after the administration of the serum it was noticed that the catheter excited a small amount of terminal bleeding; otherwise the urine was macroscopically clear, although blood was always found with the microscope. Creolin solutions were continued at intervals whenever there seemed to be any spontaneous bleeding, but there was no improvement in his general condition. He gradually failed in strength and died uremic under the care of his family physician.

The following case is introduced not only in order to show the impossibility, under some conditions, of using the creolin solution, but because it has features which are clinically interesting. It also is in further illustration of the trypsin treatment, which at the time was being tested.

A man aged seventy-five, with marked arteriosclerosis and cardiovalvular lesions with anginal attacks, inducing syncope, came under my care March 14, 1907. He stated that for three or four years previously he had experienced slowness of his urinary stream, hesitancy in starting it, and a sense of irritation in the bladder. These symptoms persisted and gradually grew worse. At first there was no nocturnal urination, but now he was obliged to urinate twice at night. About a month before coming to me he noticed that blood came with urination. He thought the blood came during the middle of the act, not with the first gush or with the last of the urination. Since then, although he has had no more blood, he has been conscious of more irritation in the bladder. His urethral length at this time was 10 inches and the residual urine was one and one-half ounce. Under treatment the nocturnal urination was reduced to a single time, and the residuum to one ounce. At irregular intervals a little blood appeared in the urine. Cystoscopy two months later revealed a projecting middle lobe of the prostate and from its posterior border a fine line of hemorrhage. No neoplasm could be found on the most careful examination. The tendency to hemorrhage was entirely controlled by applications of a weak solution of nitrate of silver. The residual urine averaged one-half ounce and he was allowed to go to Great Britain, which he did in the middle of June, 1907. He returned to my care at the end of the following September. Having had a return of the irritation in his bladder he sought advice from a surgeon in England who subjected him to violent instrumental procedures, which prostrated him and sent him to bed with fever and also, apparently, cystitis. As soon as he was able he went to Edinburgh, where he saw Mr. Annandale, who examined him carefully, told him there was nothing serious the matter and that no operation was indicated. Since then he has had severe scalding or burning with each act of urination and more or less blood in the urine has been constant. He is weak, his cardiac attacks have increased in frequency and severity and his general condition is poor. The urine contained a large proportion of blood, and the examinations of the urine now revealed epithelial deposits of different kinds which were all suggestive of neoplasm. The solution of creolin of one-fourth of 1 per cent. was begun, but the mere introduction of the catheter aggravated the pain and increased the amount of blood. After three trials its use was abandoned. I gave him gallic acid and iodide of potassium internally, and sent him home to keep quiet. In three weeks he had gained in strength, his cardiac attacks were less frequent and there was a very decided diminution in the quantity of blood, which varied from day to day. After the quiet of the night the urine was clear, but the movements of the day caused the urine to become bloody again and it was now so dark with blood that I advised him to go into a hospital where he could have proper care and be cystoscoped. Cystoscopy showed distinctly a tumor occupying the anterior portion of the superior hemisphere of the bladder, extending across the midline to the right side and downward, covering the right lobe of the prostate, and extending to the situation of the ureter on the right side. In some places it had a well-defined cauliflower-like appearance, while in others the periphery of the growth was translucent. Filmy villi floated in the fluid contents of the bladder. Irregularly shaped, elongated clots could be seen in the tissues of the mass. After a careful examination by Dr. A. A. Smith of the patient's cardiac and circulatory conditions, radical operation was advised against and it was determined to test for his benefit the trypsin treatment. It was given daily. There was no complaint of pain after the injections, excepting when the quantity was increased too rapidly. He was kept in bed and the bleeding moderated to such a degree and his general condition so improved that three weeks later the patient was allowed to return to his home at Seymour, Conn., and placed under the care of Dr. Russell of New Haven. The latter continued the daily injections of trypsin.

On February 22, 1908, the following record was made by Dr. Russell. "The patient is in excellent condition, has gained in strength, color and in general good looks. The tolerance of the bladder has gradually increased until he retains his urine four to six hours at night, and he can hold from six to fourteen ounces of urine. On his return home there was some blood in the urine macroscopically, which gradually disappeared, and of late there has been none, excepting that under the microscope a few blood discs may be seen. Today the urine is pale lemon color, and no blood is visible to the naked eye. One ampoule of trypsin has been given daily with the exception of four days, when two ampoules were given, but the pain induced seemed too great, and one ampoule was resumed, which dose has been daily given up to the present. Besides this he has taken two holadin capsules three times a day persistently. There has been no nausea nor somnolence, and no fetid odor to the urine, nor other results which have been ascribed to this method." I again examined him with the cystoscope at his home in the country. The instrument caused considerable pain in the deep urethra and deep pressure on the posterior margin of the prostate caused the patient to wince and groan. The tumor mass, as described on December 12, seemed to have shrunken, *i.e.* the area that is occupied was the same, but there were no translucent villi floating in the fluid and no cauliflower-like projections from its surface. The mass seemed more concentrated, if that word may be used, that is to say, its volume projecting into the bladder was less. Its surface of a deep red hue was irregular and the growth extended from the right

side of the prostate laterally upward to the superior hemisphere of the bladder and plainly had not extended beyond the dimensions previously described.

Dr. Russell, under date of January 2, 1909, adds: "When he first came under my care all urine at the time of urniation had a very strong odor and contained a large proportion of blood, and the indications were that he probably could not survive more than a few weeks. The foul odor and the large amount of dark precipitate present daily in the urine, consisting principally of blood, rapidly lessened and soon disappeared after his arrival at home. The urine became light straw-colored, excepting occasionally when it became pink from minute traces of fresh blood. The pain on urination almost entirely disappeared and he improved in general appearance. From the first few days after he commenced treatment his severe symptoms showed much amelioration. As to the doses of injectio trypsin I commenced with one-half an ampoule and gradually increased to one and one-half ampoules at the end of about eight days. Afterward I used one ampoule for each and every injection, solely because the injection of a larger dose caused local discomfort and some irritation. No suppuration occurred after any injection, nor did the injections appear to produce any constitutional effects. The injections were made subcutaneously over the lower two-thirds of the abdomen and in the dorsal and lumbar regions, from the scapula to the brim of the pelvis. They should not be made deeply enough to enter any muscle, for when I did so twice much unnecessary pain was produced. No local anesthetic was necessary, as care was taken to inject slowly. These injections were made every day with one exception, in February, 1908, until September 18, when they were discontinued because diarrhea and vomiting, which began on September 11, had rapidly reduced his strength and he was on the latter date so weak that it was thought inadvisable to continue the injections."

It will be noted in this case that at the first cystoscopic examination in May, 1907, only a bleeding middle lobe of the prostate could be defined. At that time the cystoscopic view was clear and the examination could be sufficiently prolonged without pain to the patient. Therefore I am confident that if the neoplasm was present in the bladder it could have been plainly seen. The relation of the traumatism to which he was subjected in England to the sudden development of the neoplasm is interesting.

No autopsy being permitted, we remain in doubt whether or not there was a metastasis to the stomach and intestines; but the prolonged nausea and vomiting and finally a hemorrhage from the intestine would seem to suggest an invasion by the disease of the digestive organs.

To talk about the trypsin treatment of cancer at this late day may seem like the "threshing of old straw," but as we learn from accumulated experience, I beg leave to add my contribution. It will be remarked that in one case the method was faithfully and systematically carried out according to the directions of Dr. Saleeby, the disciple of Professor Beard, whose writings upon the subject had attracted the attention of the profession. In the other case the method was impossible because of the patient's constant complaint of pain following the injections. Nor did it, in this case, seem to me to be a fair test, because when it was begun the neoplasm had advanced to such proportions that the result was inevitable. In the one case, however, in which there was improvement in the patient's general and local condition, it is a question whether this improvement was not due to his quiet country life with its general strengthening of his resisting power, rather than to the administration of the trypsin. Furthermore, in spite of the continued administration of trypsin, the patient became more and more debilitated, finally cachectic, and died from symptoms suggestive of an invasion of the digestive tract. It seems to me that if the trypsin method had any virtue at all it would have been manifested not only in the amelioration of the patient's local symptoms but in an uninterrupted improvement of his general condition and finally a return to health. There was, it is to be admitted, a slight change for the better in the appearance of the tumor as seen by the cystoscope, but from time to time there were evidences in the urine of débris which could be attributed only to pathological changes in the tissue of the tumor. It is also to be noted that this patient came under observation relatively early; that the treatment was begun promptly and that notwithstanding this the malady pursued its usual course. Therefore, my own conviction is that the trypsin was ineffective and that the temporary improvement was due to the patient's temporary increase of resisting power.

Similar comment may be made upon the results of my experience with the ascitic serum or the Hodenpyl method. In one case it could not be carried out because of the old man's susceptibility to pain and because of the sudden termination of his life by the onset of uremia. In the other, however, a faithful and prolonged test was carried on until the supply of serum failed; but by this time it had become evident that the progress of the malady had not been stayed. The improvement in the patient's condition, in my opinion, was due entirely to the control of the escape of blood. During the whole course of his disease up to two weeks before death, the local effect of the creolin solution was imperative—not only to control the degree of bleeding, but also to save the patient from the psychic effect of the fear that he was bleeding to death. There is one prominent fact, however, interesting to note, that soon after beginning the serum and apparently under its influence a sudden change took place in the volume of the tumor. Of this the evidences are the steady increase in the length of the urethra, indicating that the catheter had to surmount a sudden enlargement of the obstructing mass; also a sudden increase in the amount of retained urine, indicating an increase in the obstruction; and the change in the sensations conveyed to the hand through the catheter, showing a change from a soft obstructing body to one of some density or rigidity. Although these cases exhibit the failure of the serum treatment of carcinoma, they substantiate the claim that in creolin we have a remedy which measurably controls the bleeding of the tumor, and in so far retards its fatal progress, while in no sense does it control invasion of the general economy.

In such a fatal disease it might be argued that it is useless to do anything. "Leave the patient to his fate!" But life is sweet, and if the patient can be made relatively comfortable and the fatal issue postponed every means for this purpose should be employed. But in the operable cases early removal with wide resection of the bladder wall should be done even if the result be a considerable loss of

bladder function. The sad commentary upon tumors of the bladder is, that often, before the patient presents himself for diagnosis, imperceptible metastases have taken place. In my experience the tumor and bladder wall have been resected as widely as seemed justifiable, with the immediate result of restoring to the patient a fair urinary function and measure of health; while yet, in less than six months, he has developed a fatal metastasis in the kidney of the corresponding side. Notwithstanding such experience, there are enough cases of permanent cure on record to warrant the opinion that early and wide removal is the best possible procedure for the patient.

40 East Forty-first Street.

PARALYSIS OF THE UPPER EXTREMITY DUE TO NERVE INJURIES.

By NATHAN JACOBSON, M.D.,

SYRACUSE, N. Y.,

PROFESSOR OF SURGERY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY; SURGEON TO ST. JOSEPH'S HOSPITAL, SYRACUSE, N. Y.

It is not the purpose of this paper to consider all forms of nerve injuries which may produce partial or complete loss of function of the upper extremity, but rather to illustrate some usual and unusual conditions encountered by presenting the histories of a few cases. The most frequent cause of partial paralysis is probably injury to the musculospiral nerve. In cases of fracture of the shaft of the humerus because of the intimate relationship of this nerve to the bone it is apt to be damaged to a greater or less extent. It is possible that the nerve may be completely ruptured, but more frequently some of its fibers are torn or the nerve is caught between the fractured ends of the bone or in the callus as it forms, or is stretched over the callus if any marked bending should occur at the site of fracture. The nerve can also be injured at a point lower down, namely, in the lower third of the arm. Here it is not always associated with fracture. Injury to this nerve cannot always be recognized at the time of the receipt of the fracture, and indeed is usually not appreciated until repair of the bone has taken place. When the splints and dressings are then removed the characteristic wrist-drop and the inability to extend the fingers or supinate the hand are observed. Loss of sensation is likewise apparent over the lower half of the outer and anterior aspects of the arm and of the middle of the back of the forearm. The degree of damage done to the nerve will obviously determine the subsequent course of each case.

I desire to call attention to some of the features as I have seen them, inasmuch as they have differed somewhat from those outlined in the accepted works on fractures. Perhaps this can be made evident by the clinical pictures presented in two cases of injury to this nerve caused by fracture of the humerus.

Case I. Fracture of humerus with angulation; nerve not apparently damaged, but adherent to callus for distance of two inches; separation of nerve; prompt and complete recovery from paralysis.

This was the case of a young woman, 19 years of age, a telephone operator, who was brought to me by the late Dr. J. W. Eddy of Oswego on April 11, 1907. She had a negative family history and had always enjoyed excellent health. On February 5, 1907, she sustained a fracture of the humerus. Dr. Eddy informed me that he had at once suspected that damage had been done to the musculospiral nerve because of the apparent weakness of the wrist soon after the receipt of the injury. When he brought her to me she was unable to lift her hand or, indeed, move it in any way. The thumb was flexed and drawn under the fingers, from which position she was unable to withdraw it. She complained of numbness over the back of the hand and forearm. Upon examination of the arm a large callus was found. An *x*-ray picture, taken by Dr. C. E. Coon, showed angulation of the bone at the point of fracture and considerable callus.

I operated upon her April 13, 1907, making a curved incision over the humerus at the site of the deformity. I separated the fibers of the triceps muscle and had no difficulty in exposing the nerve. It was stretched over and was adherent to the callus for a distance of about two inches. It was readily separated and did not seem to be in the least damaged. The nerve was further freed for an inch above and another below the area of adhesion and a considerable portion of the callus removed. Rubber tissue drainage was introduced. As soon as the following day the patient appreciated some improvement. She was able to move the thumb almost as freely as the other fingers. The numbness had disappeared from the back of the hand. As I removed the splints in which the extremity had been placed it seemed that there was not the same degree of wrist-drop. For a few days she complained of pain along the line of the incision. In the course of three days there was further improvement in the extensor movements of the hand. Ten days after the operation we were able to note that when the arm and forearm were placed in certain positions she could hold the hand out straight. She remained in the hospital until April 28, 1907, when she returned to her home in Oswego. I did not see her again until June 11, 1908, at which time she stated to me that the improvement had been continuous from the time she left the hospital, and, in the course of three months, she was able to resume her work. At the date of this examination it was impossible to determine that there was the slightest impairment of motion or sensation in the extremity.

That such prompt restoration of sensation occurs where the nerve has not been visibly damaged will appear in the history of another case to be subsequently related. The prompt return of motion is also in keeping with what I have seen where no apparent injury has been done to the nerve structures. However, if thickening or other change in the nerve has occurred we have not observed the same prompt improvement. This is illustrated by a case recently admitted to my hospital service and operated upon by my associate, Dr. Coon, February 27, 1911. The nerve was found stretched over the callus and the bone united at an angle. The nerve was, furthermore, adherent to the bony structures and sharply constricted at one point, above which it was greatly enlarged, practically forming a neuroma, while below the point of constriction there was apparent atrophy. In this case the nerve was thoroughly freed and the wound closed with tissue drainage. Repair took place by primary union. Sensation promptly returned, but the motor function of the wrist and hand is coming back very slowly. He has still a very decided wrist-drop and can flex his fingers only to a limited extent. He has but slight grasping power of the hand, although he can pick up some things with his thumb and index finger. He remains in the hospital, being quite helpless.

Case II. Lacerated wound implicating the musculospiral nerve associated with scalp wound and injuries to the shoulder joint.

My next patient presented rather an interesting surgical problem. He was an Italian, 32 years of age, married, and a carpenter by occupation. He consulted me October 15, 1910. Five weeks previously, while driving an unmanageable horse, he was thrown out of a wagon and struck a tree. He sustained an injury to his head and right arm. He was attended by a physician at his home in Oswego. Since the receipt of the injury he had not been able to use the arm. When he came to me the right forearm and hand were bound up in splints. I found a scar in the occipital region 1½ inches in length, and another just above the flexure of the elbow on the radial side of the arm two inches in length. These scars had resulted from lacerated wounds. From the date of the injury he had been unable to raise the wrist and sensation had been greatly impaired in the forearm and hand. Upon examination I found a great deal of stiffness and fixation of the corresponding shoulder. There was no evidence of dislocation nor of fracture. Here was a man who had sustained an injury to his head, shoulder, and arm. None of the manifestations pointed to brain damage and we could readily exclude this area as being a factor in producing the paralysis of the forearm and hand. The question of a shoulder injury implicating a nerve had to be considered. Upon examination some fullness on the anterior surface of the right shoulder joint was apparent. The joint was broadened so that measurement from the mid-sternal line to the greater tuberosity of the humerus was ½ inch greater than on the opposite side. The joint motion was limited so that he was unable to carry the arm upward beyond an angle of 45 degrees from the body. An attempt to force the extremity beyond this point caused pain. The deltoid was slightly wasted, presumably from lack of use rather than because of an injury to the circumflex nerve. Sensation on the posterior aspect of the forearm was greatly diminished. There seemed to be an area of hyperesthesia on the inner surface, however. The posterior surface of the hand seemed greatly congested and was somewhat edematous. The conclusion seemed obvious that although there had been some injury to the soft structures surrounding the shoulder joint the paralytic manifestations were evidently due to musculospiral paralysis, and that the wound which he had received on the radial side of the arm just above the elbow joint was responsible for it. Subsequently I took the patient to Dr. J. H. Burch in order that he might test the electrical reaction of the affected area. He found that the sensation of the back of the hand was not entirely lost. On the left hand he could recognize the two points of the compass when separated by ½ cm., on the right only at a distance of 1½ cm. On the posterior surface of the right forearm he could distinguish the two points at a distance of 2 cm., while on the left he recognized them when the points were separated by but 2 cm. He seemed unable to compress the dynamometer with the right hand so that the pointer moved on the dial at all. With the left, however, he was able to move it to 90 degrees. In testing the galvanic reaction it was found that the left supinator longus reacted at 17 milliamperes, the right at 15. A corresponding difference existed in the extensor carpi radialis as well as the extensor communis digitorum and the triceps. The interossei also responded. In all of these muscles there was a corresponding difference in the faradic reaction. In no muscle was there any evidence of reaction of degeneration. In none was sensation or motion completely lost, but was simply modified. The conclusion was, therefore, reached that the musculospiral nerve had been damaged, but not severed. He was consequently referred to Dr. Kidder for electrical treatments. No improvement following their administration, the patient returned for surgical operation. It seemed wise to improve if possible the condition of the shoulder before operating on the nerve. For three weeks, therefore, Dr. J. J. Levy subjected the shoulder to treatment with dry heat, passive and resistive movements, and massage. These measures greatly improved the mobility of the shoulder.

On December 6, 1910, I operated upon him at St. Joseph's Hospital. Drs. Larkin, Flaherty, Blum, Muench, Palmer, and several other physicians were present. I made a horseshoe-shaped incision in the lower part of the arm with its convexity downward, the scar being placed in the center of this incision. After dissecting the flap-up and cutting away the subcutaneous tissue there was no difficulty in locating the inner border of the supinator longus muscle and separating it. The musculospiral nerve came promptly into view as the muscle was drawn aside. That it had been badly injured was at once evident. It had not been divided. The nerve was exposed for a distance of about 2½ inches; the lower inch had a diameter of ⅛ of an inch, and the upper portion was fully twice this size. For an inch and a quarter the nerve was very adherent and this was particularly the case at the point of nerve enlargement. The bleeding vessels were secured and, after thoroughly freeing the nerve, it was wrapped in eargyle membrane and buried in the muscular structures. The wound was closed with interrupted silkworm gut sutures and the extremity placed in a splint. Repair by first intention occurred. Two weeks after the operation he returned to his home in Oswego. There was at that time no material change in his condition. Sensation had not been greatly improved and there was no increase in the motor power. Dr. Kidder again took up the electrical treatment and this has been faithfully carried out. The following statement from the doctor, dated April 12, 1911, tells of his present condition: "He has been showing progressive improvement. He was able to go to work on the 27th ultimo, doing carpentry. His hand and arm were in such condition that he could handle boards and light tools and use a saw. He was, however, unable to exercise sufficient grasping force to hold a hammer in his right hand until to-day, when he used the hammer most of the day with this hand. When he first came under treatment the nutrition of the forearm was poor, and there was some circulatory stasis. At present the condition of nutrition and of the circulation is practically normal."

This case also illustrates the point that when there are visible changes in a nerve as the result of injury the restoration of function will be slow. However, the return of sensation and muscular power has been more rapid than I had predicted.

To what extent the functional activity of large nerve trunks can be interrupted by an injury which has produced no visible damage to the nerve structures is well illustrated by the case I am now to report.

Case III. Fracture of the neck of the scapula; displacement of the head of the bone; pressure upon and adhesions to the brachial plexus of nerves; complete paralysis of sensation and motion; operation; immediate improvement.

A lady, 62 years of age, was brought to me on March 8, 1911, by Dr. Bulger of Oswego. She was married; had several children and had always enjoyed good health. At the time of her injury, at Christmas, 1910, she was a robust woman. On that day she fell upon an icy sidewalk, striking her right shoulder. I am informed by the patient that she was told that she had sustained a dislocated shoulder and that an effort was made to reduce the dislocation. From the date of her injury she says that she has had no sensation in the right upper extremity and that there has been complete loss of motion so that she could not move even a finger. I was able to confirm her statements as to the complete loss of motion and sensation in every part of the extremity. There was no marked wasting of the muscles, although they were all flabby. The patient was in a very nervous condition and had suffered a great deal of pain in the arm with consequent loss of sleep. She was very despondent, being possessed of the fear that the extremity would be permanently useless. Examination showed the head of the humerus to be in proper place. I advised that an *x*-ray picture be taken. This was made by Dr Coon. He reported that the patient had sustained a fracture of the neck of the scapula, including the coracoid process, and that the head of the scapula, with its glenoid fossa, was twisted and carried forward. It was assumed that the paralysis had resulted from pressure of this misplaced bone upon the brachial plexus of nerves. The patient said that she had lost some fifty pounds in weight since the receipt of the injury, which she attributed entirely to her anxiety, sleeplessness, and generally nervous condition. An examination of the patient was made and no organic lesion found. On March 11, 1911, I operated upon her in the presence of Drs. Bulger and Flaherty and assisted by Drs. Coon and Demong. I made a "V"-shaped incision with the point directed inward and upward. The axillary space was opened. The pectoral muscles were exposed and both major and minor muscles divided. The brachial plexus was easily brought into view and carefully examined. No apparent damage had been done to it. It was exceedingly adherent, however, to the surrounding structures. This was particularly true of its relation to the scapula. I had no difficulty in freeing it from the clavicle to the humerus. The arm was moved in various directions and I found that in whatever position it was put the plexus remained free and was no longer being pressed upon. Rubber tissue was introduced for drainage and the wound closed by interrupted silkworm gut sutures. Aside from the occurrence of a very irritating urticaria, to which the patient said she had always been subject, no complications occurred and repair was prompt and uneventful. Within two days of the time of her operation sensation was absolutely restored so that the patient, while she was blindfolded, could definitely state which point on the arm, forearm, or hand was being pinched with a tissue forceps. She complained a great deal of pain in her arm. March 16, namely five days after operation, the patient was able to move her fingers and to carry her hand a slight distance outward as it lay upon the bed with the elbow supported. Two days later she was able to lift the arm from the bed and to move it to the right or the left. At the end of ten days she was up and about her room and as she carried her arm in a sling she kept up both active and passive movements of the extremity. Two weeks after the operation she had very free movement of her fingers and was able to lift her hand up quite readily as she sat in a chair. It is, of course, very early to predict the outcome of this case. However, it seems fair to assume that with such prompt evidence of returning sensation and motion we can look for complete restoration of function.

The case illustrates first how little is required to completely put an arm out of service and rob it of its sensation and motion. Without visible injury to any of the cords making up the brachial plexus the pressure upon it and the adhesions to the surrounding structures were evidently sufficient to deprive the patient of all power of feeling or motion. On the other hand it is evident that in this class of cases the return of sensation and motion is exceedingly prompt. I anticipate that the end-result will be the same as it was in the first case of musculospiral implication referred to in this paper, where in the course of a few months the patient had full use of the extremity.

When complete division of a nerve trunk has occurred the situation with which we are confronted is an entirely different one.

The case which I am about to report not only represents the clinical features dependent upon the nerve division but also portrays the course of events subsequent to the suture of the severed nerve and the reestablishment of its continuity and function.

Case IV. Complete division of the fifth cervical nerve; its secondary suture; slow restoration of motion and sensation.

A young man, 27 years of age, residing in Oswego, consulted me on October 10, 1909. He was unmarried and a boiler-maker by occupation. He presented a negative family history, had never been seriously sick, and denied ever having had any venereal disease. Eight weeks prior, while engaged in his occupation as a boiler-maker, he made a misstep and fell forward in such a manner as to permit the penetration of a piece of boiler plate into his neck. A lacerated wound was produced which subsequently became infected. Immediately upon the receipt of the injury he found his left arm motionless. Up to the time of my examination there had been no return of motion. He was unable to raise the arm or flex the forearm. He had slight motion is his little, ring, and middle fingers. In the neck there was a darkly discolored scar, four inches in length, of irregular outline, which extended upward and outward from the posterior attachment of the sternomastoid muscle to the clavicle. There was very evident wasting of the muscles of the left scapular region as well as those of the corresponding shoulder, arm, and forearm. In the course of the scar there were two very sensitive points separated from each other by a distance of over an inch. The patient was advised that an operation would be necessary, but he did not return for the same until October 27, 1909. At that time a further examination indicated that he had power to open and close his hand, but could neither pronate nor supinate it. With the extremity resting on the thigh he seemed to be able to rotate the forearm. Measurements taken at that time of the two extremities showed that three inches below the tip of the olecranon the

left forearm measured 9½ inches and the right 10¼. Three and a half inches below the acromion process the circumference of the left arm was 10 inches and the right 10½; 8 inches below this process the left arm measured 9 inches and the right 9¾. The circumference of the left shoulder was 15½ inches and the right 16.

I requested Dr. J. H. Burch of Syracuse to test the electrical sensibility and muscular reaction of the affected part. It appeared that there was an area of anesthesia extending downward on the chest to a point two inches below the clavicle. Its termination here was along a definite horizontal line. Posteriorly the anesthetic area reached down to a point two inches above the vertebral border of the scapula and from here downward and outward to the spine of the scapula and from the outer end of this prominence to the tip of the acromion process. Sensation of the arm was abolished anteriorly to a point 6¾ inches below the tip of the acromion, while posteriorly sensibility was modified but not lost. Neither the deltoid nor the trapezius muscles reacted to the faradic current. There was no reaction in the supra or infraspinatus muscles nor in the biceps or coracobrachialis muscles. There was some reaction in the teres minor, brachialis anticus, teres major, triceps, and pectoralis major and minor. In all of the muscles which failed to respond to the faradic current there was evident reaction of degeneration. The rhomboid muscles showed a sluggish faradic reaction, but no reaction of degeneratoin. The sternomastoid was normal in its response. After carefully reviewing the results of this examination we concluded that there had been a division of the fifth cervical nerve at or near the point where it joined the sixth nerve to make the first cord of the brachial plexus, namely very close to its emergence from the scaleni muscles. It was noted that pressure upon the lower one of the sensitive points in the scar produced a peculiar sensation which extended down the arm, while pressure upon the upper one caused pain which extended to the back of the shoulder.

On October 29, 1909, I operated upon this patient. There were present Drs. Coon, Larkin, Wiseman, Totman, Flaherty, Miller, Demong, and Buechler. I made an incision parallel to the posterior border of the sternomastoid muscle and freely separated the skin and subcutaneous fascia. The external jugular vein was found considerably enlarged and being directly in the line of operative procedure was doubly ligated and severed. The scar tissue was very dense, contained a number of enlarged glands, and was freely dissected away. The distal end of the fifth cervical nerve was found to be considerably enlarged and reddened. There was no difficulty in locating the proximal end of the nerve, which was found to be in a similar condition. Both nerve ends were freely exposed and sufficient tissue was cut away so that they could be readily brought together. By flexing the forearm and carrying the hand to the opposite shoulder additional relaxation of the parts was secured. The nerve ends were next united by six sutures of fine kangaroo tendon which were carried through the sheath of the nerve. The nerve ends were not freshened until the sutures were about to be tied. The reunited nerve was then buried in the scaleni muscles by three sutures. Additional retention sutures were placed above and below. The surface wound was closed with interrupted silkworm gut sutures and rubber tissue drainage introduced. The extremity was held in the flexed position mentioned by means of a Velpeau bandage. Upon the day following the operation the patient vomited continuously and an examination of the urine showed that this was probably due to acetone poisoning. There was no febrile reaction. The patient insisted that some sensation had returned to the extremity within twenty-four hours; that he could feel anything which might be drawn across the back of his hand and that he experienced a different sensation when he rubbed his fingers against each other than he had before. When the dressings were changed he complained of an intense pain in the back of his neck as if his neck would break. This continued for four days. The wound healed by first intention. On the sixth day the sutures were removed and the patient was allowed to be up and about. The extremity was held immovable by a Velpeau bandage until he left the hospital, November 14, 1909, when it was transferred to a sling. At that time there was very marked improvement in sensation and the anesthetic area was reduced two-thirds. Upon his return to Oswego Dr. Kidder began the use of electricity. This treatment has been carried out faithfully and has not been as yet entirely discontinued. He employed the galvanic current, using an ample and very wet sponge which he placed over the vertebræ at the back of the neck, while an electrode with a smaller sponge was applied to the electrosensitive points of the affected extremity. At first it required a very harsh current to secure a response. During the first six months he received daily treatments. After a time muscular contraction was secured on the make of the current. Sometimes it was necessary to produce a number of makes and breaks ranging from five to thirty before the contractions would commence. Apparently for weeks the treatment seemed to be fruitless in its result, but in the end the electrical responses rewarded the effort. At no treatment was the number of makes and breaks of the current less than 500. After the first evidence of improvement there was never a fortnight but that further improvement could be noted. The gain in the deltoid muscle was the first to be observed and was in the beginning most rapid, although last fall there seemed to be evident retrogression in this muscle. It was noticed that quite uniformly sensation would return before the underlying muscle showed any improvement. At times this sensitiveness would be so great as to interfere with a treatment. The patient was given a faradic battery which he used at home and in addition he used an arrangement of pulleys whereby he developed the muscular movements of his wrist, arm, and shoulder.

He returned to me for observation on different occasions. On December 15, 1909—one month after his return home—I found that he was able to close the hand more firmly. There was a slight decrease also in the extent of the anesthetic area. Four months later, namely six months after the performance of the operation, sensation was quite completely restored. At that time he was able to swing his arm forward and upward. The strength of the left hand had greatly increased. With the right he was able to compress the dynamometer to 90 degrees, with the left it measured 50. None of the movements of the arm, however, had been restored. On September 16, 1910, when he next visited me, there was very marked improvement. He was able to carry the arm upward and forward. He was no longer obliged to fling it about as if it were a flail but was able

to carry it toward the opposite shoulder by deliberate muscular movements.

A letter received from Dr. Kidder, dated April 12, 1911, states that he is still giving the patient one galvanic treatment a week. There has been, he writes, steady improvement in the muscular control and the improvement has been in the same definite ratio which has been evident during the past fifteen months. Sensation is normal except over the posterior surface of the thumb. For a time sensation was abnormally acute in places, but this is no longer the case. The deltoid muscle is now showing some sensitiveness to the current. It possesses some ability to contract voluntarily but will not as yet raise the arm. The posterior muscular fibers respond better than the anterior. The teres and subscapular muscles are not possessed of the normal innervation and do not voluntarily coordinate with the deltoid. Apparently the muscles which have been most tardy in showing improvement have been those supplied by the middle cord of the plexus. The general nutrition of the arm and shoulder is now good and the individual muscles stand out clearly defined. The patient can readily and forcefully flex his forearm on the arm and having so flexed it can hold it against a vigorous pull. He is working daily and has been for many months.

A few remarks might be in place as to the results attending nerve suture. If a nerve be repaired soon after its division has occurred the operation is called primary suture. If it be done at a later date it is spoken of as secondary suturing. It would be natural to assume that primary suture would be attended by better immediate and more satisfactory end-results. Experience, however, has not proven this to be true. If the muscular tone of the affected part has been maintained by the use of electricity, massage, passive movements, and similar measures there is practically no difference in the result to be secured whether the suture be done at once or at a subsequent period. Immediate suture has not the unqualified endorsement of surgeons with large experience in nerve surgery. Victor Horsley makes the statement that where clean division of a nerve has occurred and the wound has healed by first intention its suture should not be undertaken until at least eighteen months have elapsed and every effort has been made to secure restoration of function without operation. On the other hand, if suppuration has occurred in the wound and repair has been by granulation the spontaneous regeneration of the divided nerve is not to be expected. Such cases always require a secondary operation. In the return of functional activity after nerve suture much depends upon the degree of atrophy of the affected muscles. If this has advanced to a marked degree the period of recovery is always greatly prolonged. It is evident that after the operation of nerve suture healing by first intention is essential. It is equally important that the sutured nerve should not be subjected to the danger of adhesion formation. The cases embodied in this paper make it very clear that adhesions can completely deprive a nerve of its functional activity even when the vitality of the nerve has not been otherwise impaired. To avoid this complication the implantation of the nerve in a muscular bed or its envelopment in cargyle membrane seems to me most efficient. It is not within the province of this paper to discuss the various operative procedures of nerve splicing, grafting, or other measures to be resorted to when nerve ends cannot be approximated otherwise.

Our last case illustrates in a most emphatic manner the importance and great value of the after-treatment in these cases. Where a nerve has been simply stretched over or caught between fragments of bone or entangled in a callus or bound down by adhesions and where no visible damage to the nerve substance has occurred it can be readily seen from the cases presented in this paper that the return of functional activity is prompt and satisfactory without the energetic and long continued use of such therapeutic measures as electricity, massage, hydrotherapy, or the like. But when a nerve has been evidently damaged and most certainly when it has been completely severed the after-treatment is quite as important to the restoration of its function as is the surgical operation which seeks to remedy the local damage done. It must also be thoroughly understood that whether primary or secondary suture has been undertaken the long continued application of these measures will be found necessary. Many months may elapse without apparent improvement. The treatment must not be abandoned. The end result will well reward the effort.

Secondary suture has been performed as late as nine, eleven, and fourteen years after the receipt of the injury and marked benefit has attended the surgical treatment.

430 South Salina Street.

RECOLLECTIONS OF CHOLERA EPIDEMICS IN RUSSIA.

By G. A. FRIEDMAN, M.D.,

NEW YORK,

CHIEF OF THE INTERNAL MEDICAL DEPARTMENT OF THE MOUNT SINAI HOSPITAL DISPENSARY, VISITING PHYSICIAN TO THE BETH DAVID HOSPITAL.

So much has appeared about cholera in the lay press during the last few weeks, that it appeared to me of interest to jot down on paper some of my reminiscences of the three cholera epidemics in the fight against which I took an active part. It may be that some things I learned at the time may prove of use in any possible epidemic in this country. These epidemics took place in Russia in the years 1892, 1893, and 1894; in the two earlier years I was a medical student and worked in the region of the Kama and Volga Rivers, during the summer epidemics in that region; in 1894 I was in independent charge of the "cholera barracks" near St. Petersburg. My work consisted of treating cholera patients removed to the "cholera barracks," which were specially constructed isolation places, prepared before the outbreak of the epidemic; in addition, it was my duty to travel about and be on the lookout for any fresh outbreaks. In a word, I occupied the position of what in Russia is termed "sanitary physician."

In 1892, when first sent to the region of expected cholera, I traveled by rail, carrying with me two textbooks on cholera, those of Rossbach and Riedel; the journey lasted eight days and I had ample opportunity of reading these books twice, from cover to cover. On arrival, my chief instructed me to repair to the barracks that were situated on the banks of the Kama River, about three miles from town. There I found no patients whatever, and surprised to learn from a colleague, who reached his destination six weeks ahead of me, that he had drawn his salary during that period without having treated or seen a single cholera patient. At first my duty consisted in visiting the river steamboats

and hurriedly looking over the steerage passengers. After a few casual interrogations, I would sign the health list and let the boat proceed. There was no cholera in the town either, and meanwhile we treated the poor of the town for every possible affection with which they happened to be afflicted.

In the two weeks following my arrival we suddenly realized that the number of patients complaining of diarrhea gradually and steadily increased. There was no bacteriological work done, as it was extremely difficult in Russia to find enough doctors or students even to do the general medical work, and we registered these cases as those of simple diarrhea. When we communicated these facts to our experienced chief, he immediately removed from the city to the barracks. He called our attention to these diarrheas and made it plain that for him they were a sign that the enemy was before the gates. To our surprise he was attacked that same night with severe vomiting, profuse watery diarrhea, and cramps in the calves. Although I recognized in him the symptoms of cholera, after my book acquaintance with the disease, I called in two other colleagues from the town and they confirmed the diagnosis of Asiatic cholera. He went through a severe attack of the disease, yet recovered without any treatment whatever; he was a confirmed skeptic and "therapeutic nihilist," and steadfastly refused to subject himself to any procedure or take any drug suggested by his colleagues. After his recovery we discussed the problem of his being the first victim of the disease. He knew of no other source of infection except a waiter in the town club where he dined on that day. The waiter complained of suffering from diarrhea and was given some prescription by our chief. The latter thought it probable that the infection was transmitted to him by the dishes handled by this waiter, who was suffering from a light attack of the disease, similar to that seen by us. After this, patient after patient was sent us from the town or was taken by us off the steamers, so that my book knowledge of the disease was soon enriched by actual experience. I do not recall the actual figures, but am sure of having treated between one and two hundred patients suffering from cholera in our barracks alone. The first case, that of my chief, taught me early that during epidemics any light or severe case of diarrhea must be considered as suspicious, and in the next two epidemics such cases served for me as "barometers" of approaching outbreaks in any village under my observation.

In New York it may be advisable for all physicians to be on the lookout for just such cases of unexplained diarrhea, and, if more cases of cholera appear, these diarrheal patients should be reported to the Board of Health; especially, the physicians in the dispensaries should not treat such cases lightly. So far as actual facts are concerned, I have, of course, noted no increase in diarrheal diseases among the adults in the dispensary of the Mount Sinai Hospital and see no reason for any uneasiness at the present time.

As is well known, the comma bacilli enter the human body through the alimentary canal, and here the mouth plays an important rôle as the portal of entry. Persons suffering from chronic gastrointestinal disorders are, therefore, more predisposed to infection than normally digesting people; especially achylia gastrica and any hypoacidity are two important etiological factors in the development of the disease, for free hydrochloric acid is inimical to the bacilli. Fasting stomach, of course, in the absence of protective acid gastsic juice is likewise a favorable place for the growth of swallowed germs. This latter truth I experienced strongly enough on my own person in the third epidemic. It was on a Monday morning, when the number of cholera patients was always very large, because of the alcoholic excesses usual among Russians on Sundays. I was called by a nurse early in the morning to attend to a newly arrived moribund patient. I had no time to take breakfast. In the barrack I found the patient already in a hot bath; I bent over him and that moment he vomited, the vomitus striking me in the face. That night I fell ill with Asiatic cholera. As I was spared during the two preceding epidemics, when we were always careful to eat breakfast before starting our daily work, I am sure that the condition of my stomach at the time was the deciding factor in not helping me to escape the infection to which I was exposed. This experience may prove useful to such physicians as are now exposed to cholera in New York City and vicinity. Of course, "contagiousness" of cholera, in the sense of measles or scarlet fever, cannot be even considered by anyone who has had any experience with the disease. In further proof of the fact that mouth infection is the important one in cholera stands the frequent appearance of the disease among priests after funerals; usually their cleaner habits protect them but the custom of the Russian Orthodox Church requires that they partake of food and drink in the house of the relatives after the funeral is over. The priest thus becomes infected through the food prepared by the very hands that came into daily contact with the dejecta and the vomitus of the patient. Especially is the danger large when the peasants hide the true nature of the disease from the priest, as they frequently do. It must be understood by the American reader that during the frightful mortality of epidemics a great number of patients are not seen at all by the doctors, of whom there are always too few in Russia, and death certificates are an unknown luxury at such times. With the exception of the class of priests, cholera, just as typhus fever, is the disease of the "proletariat," for, of course, dirt and misery are the important etiological factors in the disease. So far as direct contagiousness of the disease is concerned, there is no question that a cholera patient under ideal conditions may remain in the general ward and be of no direct danger to others. Of course, most minute care must be taken to have the so-called "individual precautions" exercised in case of typhoid fever, for instance, carried out religiously in the case of cholera. But one danger remains in the presence of a cholera patient with other sick people: sickness and "run down" condition greatly diminish the resistance to infection with cholera, as is amply proved by the great number of cases among the overworked doctors and nurses in Russian epidemics.

Alcohol is a direct predisposing factor to cholera, even beside the anacid gastritis so frequent among drinkers. No other reason could explain the great number of Monday morning cholera cases even among casual drinkers. The drinking of raw water should be cautioned against during epidemics, as it is a frequent source of infection. I saw a remarkable case of "cholera sicca" in a laborer, fourteen hours after drinking some Volga water. He died in three hours after onset, having shown no vomiting, no diarrhea, but only very severe cramps

in the muscles. The people in America should be cautioned, in addition, of the danger of the various "soda fountain" drinks and the ice water.

A curious predisposing factor is the nervous fear of the disease, "cholerophobia." Every physician knows that even simple nervous excitement can produce diarrhea, that is, increased peristalis, and this seems to be sufficient to favor infection of the gastrointestinal tract. I well remember a merchant who disinfected all the money received by him by means of carbolic acid, washed his hands almost hourly, and was afraid to handle the newspapers, but fearfully asked news of the cholera situation from his neighbors. He was one of the first to be stricken with the disease. Cheerfulness is, therefore, not at all a bad prophylactic measure against cholera.

It is not my purpose to discuss the diagnosis of the disease, for there exist excellent treatises on the subject. It must be said that early in an epidemic, bacteriological examinations are of the utmost importance. Later, the clinical picture is striking: profuse diarrhea with "rice-water" stools, vomiting, muscular cramps, especially in the calves, hoarse voice, so-called "vox cholerica," and, finally, complete anuria. Cases occur, however, that never come to the "stage of manifestation," muscular cramps alone occurring. Such cases are usually fatal, as in the above-mentioned instance. Light forms of the disease show vomiting, diarrhea, and cramps in muscles but not of severe nature. Such cases are frequent in Russian epidemics and are there termed "cholerina," which must be distinguished from "cholera nostras." The so-called "cholera typhoid" is the one difficult form for diagnosis; it usually follows an attack of cholera and is accompanied by fever, while in cholera, of course, the temperature is always subnormal. Such cases sometimes extend over several months.

To mention a few experiences in the treatment of cholera, I would state that of the great number of methods suggested I have found in the algid cases hot baths to be of occasional use; they frequently lead to cessation of diarrhea and vomiting and relieve the cramps. The latter are also helped by rubbing the skin with brushes moistened with camphor or soap liniment. Most important is the treatment of cases of moderate diarrheas and of cholerina. We treated the former by administration of salol, giving about gr. viii three or four times a day. This and the usual antidiarrheal diet was frequently sufficient. In more severe cases, where nausea was marked but no vomiting, ipecac was given and vomiting was produced by giving much warm water and tickling the fauces. This treatment, of course, is more or less heroic and must be used with caution. If these methods did not relieve the diarrhea we gave constipating drugs, such as pure resublimated naphthalin, gr. ii-viii, or benzonapthol in the same dosage several times a day. Tannalbin was unknown at the time. I believe it should prove useful instead of the last two drugs mentioned. Calomel has seemed of use but in very rare cases, while it did harm very frequently.

I should like to warn against the use of opium in any case suspected of cholera. A Priessnitz compress continued through the night may be used instead to quiet peristalsis. Our patients were kept in bed when possible and were given to drink much strong Russian tea. Red wine, especially the French Bordeaux, may be added to the tea. In cases of cholerina, salol was begun as above, but if the symptoms did not respond to treatment, hot baths were begun. The duration of the bath was from 15 to 30 minutes, and the temperature as hot as could be stood by the patient. Injections or irrigations (Cantani's enteroclysmata) proved useless in my experience.

Of course, the existence of an efficient Board of Health, such as we have in New York City, minimizes the danger of a severe epidemic. Yet, if many cases are imported, regular and thorough inspection of lodging houses and the overcrowded tenements people by recent immigrants should be carried out. The press, of course, should be utilized to acquaint the mass of the people with the usual and simple methods of prophylaxis. Prevention prove an instructive example to the world of what can be done in an enlightened community by an enlightened set of officials.

CHEMICAL AND BIOLOGICAL AIDS IN THE EARLY DIAGNOSIS OF GASTRIC CANCER.

By A. E. AUSTIN, M.D.,

BOSTON, MASS.

The difficulties of early diagnosis of gastric carcinoma before the presence of a palpable tumor have been almost insurmountable. The symptoms, too, even where the malignant process has begun are so similar in many respects to those of functional disturbances of the stomach that, when pain and vomiting are sufficiently advanced to permit us to suspect the presence of a growth, exploratory operation often finds the disease advanced far beyond the point where a radical removal is possible; hence in spite of the disappointments that chemical and biological examinations of gastric contents have afforded, we are constantly on the lookout for some means which will afford us the desired information at a period early enough to afford a radical cure by the aid of surgery. Such means will be briefly summarized in this short review with the latest verdict derived from the analysis of a large number of cases in which the true diagnosis has been established by operation or autposy.

Hydrochloric acid, organic acids, and blood.—Graham and Guthrie of the Mayo Clinic at St. Mary's Hospital, in 150 cases of gastric carcinoma, verified by operation, found free hydrochloric acid in 70 cases; free hydrochloric acid without blood, lactic acid, or food remnants was present in 46; blood was present in 80 cases, while blood and lactic acid were present in 20. Blood and food remnants were present in 15, and blood, lactic acid, and food remnants in 30. Food remnants were present in 62 and lactic acid in 64. The explanation of the difference in these instances from the usual classical description of the findings in gastric cancer consists in the fact that the patients are operated upon before reaching the stage where there is absolute loss of hydrochloric acid and extensive stasis.

Hemolysis.—Frye and Lefman found that the wash water from 14 cases out of 17 non-malignant gastric affections possessed hemolytic power, especially when the gastric content contained bile or trypsin; this difficulty may be overcome by quantitative determination of the hemolysis, which the authors did not carry out. Furthermore, by carefully washing out the fasting stomach in the early morning, according to Graefe and Roehmer, the wash

water can be obtained entirely free from bile coloring matter and hence from duodenal contents. The contents of a prolapsed stomach, however, form an exception to this rule and much more are the contents after a test breakfast liable to be bile stained and hence presumably contain duodenal contents (trypsin). These authors found in 26 cases of certain gastric cancer a positive hemolysis in 22, while in 60 non-carcinomatous gastric diseases and in healthy individuals a positive result occurred only once. Furthermore, they claim that a positive test may be found at such an early period that other physical signs may be wanting. Kuntz examined 27 cases and found hemolysis in all cases proven or suspected to be carcinomatous, while it failed in all cases which clinically showed no evidence of cancer. Sisto and Jona found in seven certain gastric carcinomata a positive result, while in two cases suspected of cancer, in four gall-bladder cancers, and in 16 benign gastric affections the test was negative.

Anaphylaxis.—Livierato has shown that, when neutralized normal gastric juice filtered through a Chamberlain filter is injected subdurally into animals which have been previously treated with extract of mammary cancer, no symptoms of anaphylaxis occur, nor does the juice in gastric ulcer produce any effect. But, if the juice of gastric cancer is injected, then marked signs of anaphylaxis occur (fall of temperature 1 to 1.4° C). Apart from the fact that the fall of temperature in those prepared animals, injected with normal gastric juice, did not vary so very widely from those injected with the contents of gastric cancer, a characteristic which is made much of by Pfeiffer and usually more significant than symptoms, the method would be found very inconvenient, as the material could not be readily obtained except in a large clinic unless a permanent preparation could be made; nor was the number of cases mentioned enough upon which one could base definite conclusions as to the consistency of this phenomenon.

Amino-acids.—Amerigo Barlocco has found that when gastric contents removed after a test breakfast are neutralized and neutralized casein added, upon being placed in a brood oven, a moderate increase of the amino nitrogen is found in both healthy individuals and persons suffering from benign stenosis (gastric) amounting to 0.4 to 0.515 per thousand parts. When, however, in five cases of gastric cancer, the amino nitrogen was determined in the same way, it amounted respectively to 0.8, 1.315, 0.9, 1.4, and 1.2 grams per liter; even when the stomach was thoroughly washed before the test breakfast was given the results were the same.

Urine pepsin.—Takeda found in six cases of achylia gastrica that pepsin was present in the urine when edestin was used for its determination. In nine gastric carcinomata, on the other hand, pepsin was absent in three instances; in two very small in amount, while in all the others it was present but in varying quantities. The amount of variations in the results obtained by various workers with this method, according to this author, may be due to the time of day at which the urine is collected. This can be overcome, if all workers would use for the test a portion of the whole day's urine. The presence of pepsin in the urine in gastric cancer seems to depend very largely on whether it (the cancer) is diffused or circumscribed; in the former case the ferment is usually absent. On account of this lack of uniformity the presence or absence of pepsin in the urine is not adapted to the early detection of gastric cancer. Ellenberger and Sholz have found that when the urine contains a marked amount of pepsin, while the gastric contents contain little or none, it points very strongly to a gastric carcinoma. On the contrary, a large proportion of the gastric achylias, with which the former may be confounded clinically, had pepsin neither in the gastric contents nor the urine. As can be well seen the marked confusion in the results of these authors mentioned is such that it will require the examination of a vast number of achylias and gastric carcinomata before the value of this test can be clearly shown or completely disproved. If it can only be made a routine in clinical laboratories, we shall soon obtain something definite on which we can work.

Peptid splitting ferment in the stomach.—Neubauer and Fischer have found that three sources of error may arise in the detection of this peptid splitting ferment in the gastric contents of carcinoma. First, tryptophan may be found in the gastric contents themselves; secondly, peptic splitting bacteria may make their way through into the stomach, or there may be present pancreatic juice containing trypsin, or blood may be present (inhibitory action). The splitting of an added glycyl-trytophan is a very reliable test for gastric carcinoma, if these sources of error can be excluded. In 26 normal individuals with gastric diseases other than carcinoma the test was always negative; while in 17 cases of positive carcinoma of which 5 were operated, or a post-mortem diagnosis made, it only failed twice, and in these only vomitus could be obtained. Lyle and Kober have made use of this test in a series of 21 cases and found it very valuable. In 11 cases which were operated upon it never failed, when present, to show the presence of cancer and, when absent, the case turned out to be cancer elsewhere or cholecystitis, which had been falsely diagnosed gastric cancer. As with the hemolysin test, the errors are usually due to the presence of trypsin in gastric contents due to regurgitation; the latter can be avoided much more readily if the test meal be given in the afternoon and the stomach washed out before it is given. A laxative given the night before also increases the certainty that the stomach is free from duodenal contents. Weinstein does not believe that it is necessary to test the stomach contents for tryptophan before the glycyl-tryptophan is added, since he claims to have found that the detection of tryptophan in the gastric contents is practically as effective an evidence of gastric cancer as the subsequent splitting of the peptid by the gastric contents. He further believes that a preliminary test should always be made for bile in the gastric contents; if bile is absent, the possibility is excluded that duodenal contents and hence trypsin have made their way into the stomach. The author has modified the test as follows: Four or five hours after a regular meal some stomach contents are obtained, filtered, and tested with bromine water for tryptophan. If the reaction is positive (violet color) one may conclude at once the probable presence of gastric carcinoma. If absent, some of the filtrate transferred to a stoppered bottle and treated with a little toluol is put into the thermostat and tested again for tryptophan, 24 to 48 hours later. Some of the deficiencies of this test which are pointed out by the author are its inconstancy; the

reaction may be present in one specimen of stomach contents and absent in another from the same patient; hence it is always desirable to test three or four specimens from the same patient at different times. A mixture of coloring matter or the presence of blood or coffee grounds interferes very decidedly with the performance of the test. When, however, the hemorrhage of the stomach is pronounced the case has advanced to a point where we do not need this test. Free hydrochloric acid interferes very decidedly with the activity of the cancer ferment or may destroy it altogether, forming a very serious obstacle to the employment of the tryptophan test. The only fortunate feature with reference to this obstacle is the frequent absence of free hydrochloric acid in the gastric contents of cancer.

Taken as a whole we find practically the same difficulty in all these tests, as far as certainty of diagnosis goes, apart from merely inhibitive influences like free hydrochloric acid and blood, and the presence of duodenal contents in the stomach. As long as the pyloric portion of the stomach and the duodenum are such near neighbors this interchange of contents will always prove fatal to absolute accuracy in diagnosis of malignant disease of the stomach by these means. When we consider how readily the duodenal contents can be drawn into the stomach by the slight efforts made at vomiting by the patient when the tube is introduced or the ease, according to both Einhorn and Boas, with which under certain conditions the end of the stomach tube may make its way even through the pylorus into the duodenum, we can clearly see what reservations must always be made in a diagnosis obtained in this way. Again, it is not certain that with duodenal contents in the stomach bile must always be present and, as is well known, the trypsin of the pancreatic juice and the cancerous enzyme do not differ markedly in their action. Furthermore, on account of the animal diastase in the stomach, derived from the saliva, and the alleged presence of a fat-splitting ferment in the same, we have actually no means of determining whether we are dealing with a secretion of a malignant growth or with pancreatic juice. Nor do I think it probable that merely washing out the stomach or giving a purgative will prove efficacious in resisting the encroachment of the duodenal contents on the stomach. In my own clinic I have made use of the tryptophan test, as modified by Weinstein, as a routine part of the examination of gastric contents, and have more faith in its absence as a means of excluding malignant disease of the stomach than in its presence as demonstrating this condition. In a series of twenty-two unpublished cases of my own it has been absent in twenty, though among them were included five achylias, and present in two; in one of these latter there were marked stasis and a palpable tumor, while in the other neither of these features was present, though other symptoms pointed strongly to malignant disease situated elsewhere than at the pylorus. Of course when the contents were bile-stained no effort was made to apply this test. The tryptophan test seems to me to be the most available of all these tests for a clinic, requiring the least in equipment and being the one most easily carried out; in the meantime only extensive applications will prove its diagnostic value.

The determination of the nitrogen content of stomach washings either by the Kjeldahl process or by the determination of the protein content with an Esbach tube has proved in my hands of very little value. At most it simply indicates a probable stasis with the presence of a large amount of mucus, which can come equally as well from an innocent gastritis as from that which is associated with gastric cancer. So far as we are able to determine the secretion of a malignant growth does not contain any peculiarity in its protein content by which it may be designated as such, and until such peculiarities are found we are obliged to rely wholly upon its contained ferment, which, as has been stated, does not differ from the proteolytic ferment of pancreatic juice.

SOME EXPERIENCES WITH "RUSSO'S TYPHOID FEVER TEST."

By F. W. ROLPH, A.M., M.D.,
TORONTO, ONT.,
ASSISTANT IN CHEMICAL PATHOLOGY AND CLINICAL MEDICINE, UNIVERSITY OF TORONTO,
AND
W. HARPER NELSON, M.B.,
TORONTO, ONT.,
LABORATORY INTERNE, TORONTO GENERAL HOSPITAL.

Early in 1905 Russo described in the *Riforma Medica* a new urinary test which gave a positive reaction in typhoid fever, measles, smallpox, and in some cases of severe tuberculosis. It is performed as follows: To 4 or 5 c.c. of the patient's urine add four drops of a 0.1 per cent. aqueous solution of methylene blue; mix well and examine against the light; a mint or emerald-green coloration is positive, whereas any blueish tinge renders the test negative. Russo reported the reaction as being unaffected by boiling or by the ingestion of such drugs as calomel, quinine, salol or caffeine, and also pointed out that the gradual resumption of the bluish tinge, as the patient advanced in the disease, was a valuable and favorable prognostic sign.

During the past year we have been employing this test, as a routine proceeding, on most of the cases entering the Toronto General Hospital, and can vouch as to its efficacy as a diagnostic aid in typhoid fever, if applied early enough in the disease. Un-

fortunately a great many of the enteric cases have been ill two weeks or more before entering the hospital, and their urines, showing as they did a returning bluish tinge, had to be discarded in our results. The following list of cases, all of which were found to be typhoid by positive agglutination tests, or by blood cultures, gives some idea as to comparative results between this reaction, and the ordinary laboratory methods. All tests were carried out within forty-eight hours after admission.

Patient	Probable Day of Illness	Russo	Diazo	Widal	Leucocyte Count

*Typical symptoms, positive blood culture, widal negative until late in the disease.

†Unusual case with periods of subnormal temperature.

In addition to the above list we have obtained positive tests on many outside cases, but as complete contemporaneous laboratory examinations were not performed, they are not included here. We did not examine the urines of any measles or smallpox patients, but obtained a few positive results in tuberculosis. In non-typhoid patients we made a great many examinations, with invariably negative results, except in the above mentioned tuberculous cases. Especially did we concentrate our attention on conditions which are apt to resemble typhoid at the outset, viz.: Influenza, Endocarditis, and slight septic states, but in no case obtained the typical green color.

There is one important fallibility of the reaction, which at first bothered us a great deal, until one of us discovered the cause, viz., that urines containing bilirubin will give a reaction which differs so slightly from the typical green, that they cannot be used in employing the test. We thought then that perhaps the results in typhoid were due to the presence of small amounts of bile, but this could not be demonstrated in our positive typhoid urines. This difficulty undoubtedly militates against the success of the reaction.

To sum up, we may say: (1) This test is very simple and easily performed, but one should have seen the typical color once or twice to be sure of one's results. (2) Bile should be tested for, and in the event of its presence, the urine should be discarded. (3) The earlier in the disease the more likely and the more typical the reaction. This is very important, as it differs, in this respect, from other laboratory tests, except blood culture. (4) The slightest tinge of blue must call for a negative interpretation, though experience will often enable one to distinguish the returning blue tint of a convalescent typhoid patient, from that of a normal or non-typhoid urine. (5) The reason of the mint or emerald-green color is doubtful, but it is probably a reduction test, depending upon the presence of unknown bodies in the urine. (6) We did not find the gradually returning bluish tinge of much assistance in prognosis, as so many of the dangers of typhoid are, as it were, accidental, and not directly dependent upon the severity of the infection.

IS ALCOHOLISM A DISEASE?

By F. H. BARNES, M.D.,

STAMFORD, CONN.,

MEDICAL SUPERINTENDENT OF THE DR. BARNES' SANATORIUM.

The trend of opinion of the medical profession during the last decade has shaped itself to the idea that "alchoholism is a disease." Inebriates are pleased to accept this doctrine as a pallium for their shortcomings, and when advanced by respectable members of the profession this conception of alcoholism has weight. It proves an attractive field for less conscientious therapeutic promoters, lay and professional.

The late Mrs. Eddy, of Christian Science fame, certainly came nearer the truth when she applied her doctrine that "there is no such thing as disease" to the problem of alcoholism, and the fact that members of her cult were cured of their alcoholic habits by fervently believing that there is no disease goes far to demonstrate that, even with such undesirable means of suggestion, a "disease" can be eradicated which is no disease at all. I have called this suggestive method undesirable because it works upon the superstitions of people who have not learned to think for themselves. Now and then some hitherto unconverted infidel feels impelled to proclaim "I am saved," and, lo and behold, from that moment he is supposed to go forth and sin no more and drink no more. These successful "cures," even if they do not prove permanent, show the power of suggestion and persuasion. It is probable that in this way more persons have been cured of alcoholism than by all the medicine in the world, for the simple reason that in alcoholism we are not confronted by a disease curable by medicine alone.

It is quite feasible to compound drugs which have the effect of rendering the odor of alcohol a "stench in the nostrils," and while this effect lasts the patient is cured. But the effect is not permanent, and as the medicine soon palls upon those who have submitted to this kind of treatment it is discontinued if for no other reason than that they are only too pleased to quit a remedy that debars them from the use of their erstwhile favorite drinks. Thus in a short time they are back again to their old habits, perhaps even using a larger amount of alcohol than before, owing to the forced abstinence during the so-called cure.

It is a fact that no person ever has been permanently cured of alcoholism unless he was willing to be cured and morally strong enough to stay cured. Medicine is quite incapable of imparting to the individual the necessary will power to achieve this end. That this individual will power is an absolutely necessary factor in the problem is best illustrated by the so-called new year's resolution. Many are made every year and many have been broken. The number is probably equal, although there is no doubt that the majority of resolutions are made in good faith, but the will power is lacking to keep them. Nor is it altogether the fault of the resolution makers, it is the old surroundings, the old friends with whom they are unable or unwilling to part with that prove their undoing, especially in the absence of any moral suasion or support. That they themselves feel the necessity of such support is evidenced by the fact that they select the first day of the year for starting a new life, for if they were strong enough in themselves to abstain they could do so on any other day of the year whenever

they felt particularly keenly the disgrace and other evil consequences they had brought upon themselves and their friends. They could frame their resolutions any time, but knowing their own frailty in keeping them they trust to the elevating influence of the new year for support. They trust in vain. As the charm of the resolution wears off (in most cases already on the day it was made) they return to their former habits.

Comparatively few people have sufficient control of their will to break with evil habits and surroundings. They are not alcoholic patients but patient alcoholics, and it is the task of the medical profession to rouse their lethargy, not by filling them with medicine, but by inculcating moral force and will power which alone will enable them to resist temptation. It might be urged that, alcoholism not being a disease entity, it is not the physician's function to administer to its victims, but rather that of a mental healer, a clergyman, or a Christian Science practitioner. Some reflection, however, will show, as indeed experience has shown, that this is an erroneous view. Inebriates seldom have freiends of opposite proclivities to their own; here the uneven poles do not attract, but repel each other. Parents are out of the question, because parents who have not had sufficient authority over their children while growing are quite unable to control them after they have grown to be drunkards. Clergymen are not sufficiently in touch with the indulgent class to command their confidence, and the religious trend they are prone to infuse into their ministrations is an impediment to their success. Unfortunately they are not, as a rule, endowed with a practical knowledge of men and women of the world. Mental healers and Eddyites are on the wane and opportunities are more frequently presenting themselves for the legitimate psychotherapeutist to retrieve the honors which have been shared by religious paranoiacs and sane scoundrels. The physician alone is the one most capable to arouse the latent will of the alcoholic. He commands the situation by virtue of his training and experience.

It has been mentioned that old friends and surroundings form insurmountable obstacles to permanent improvement. A change of friends and locality alone would not suffice to ensure success, because an individual with weak will would succumb to the temptations of new friends and new surroundings. Well-meaning members of the laity lack the energy begotten of knowledge which carries the best influence for good. It is generally conceded that institutional treatment brings about the best results in the treatment of alcoholism, as it does in many other conditions of weakened will and mental enfeeblement. The constant guidance of an experienced physician, new and elevating environment, the various mechanical and hydrotherapeutic accessories all have their physical and psychical effect for good. The training he thus receives will be so strong and effective that it will never be forgotten or discarded. He must be made to understand that his own will power is needed to break the habit, and that no treatment can impart or increase the will power. Medicine in these cases is only useful to restore disturbed function.

Be it understood that when an alcoholic is simply physically restored and the individual then returns to the outer world, he will, by the very vigor he possesses, be inclined to partake of more alcoholic beverages than his impaired organism is able to bear. It is clear, therefore, that the strengthening of the will power is the only permanently effective factor in breaking the alcoholic habit. He must be taught that he is not to submit to coercion, that he must not say when the temptation to drink besets him "I *must* not," but "I *will* not," and by the exercise of such will power he will be physically and morally a stronger and better man. All this cannot be achieved by a course of medical treatment. Medicine can only benefit the physical condition and it is time, therefore, that it were universally recognized that alcoholism is not curable by drugs, but is a weak and mischievous habit that can only be broken by properly educating the will power in the right direction.

Allow me to cite a few cases in illustration of the effect exerted by the treatment I have outlined. They are not especially selected as being more than usually noteworthy, but are simple illustrations of every-day practice in the sanatoriums.

Case I.—Physician, entered my sanatorium for treatment in December, 1908. He had been in the habit of taking 15 grains of morphine, 30 grains of cocaine, and more than a pint of whiskey every day. We instituted the gradual reduction plan, removing the liquor first, then the cocaine, and last the morphine. At the end of three months he took no drugs of any sort and was rapidly getting into first-class condition. But this was only the first and smallest part of the treatment. The patient, after having been free from drugs for two weeks, wanted to go home, but we advised him in a friendly but decisive way to stay in the sanatorium for at least another three months. During that time we had many heart-to-heart talks, in which I convinced him that his future career and success, quite aside from his health, depended upon a process of self-education which would enable him to resist the temptation to all drugs and drinking. I appealed to his pride, to his obligations toward the profession. I showed him the financial aspect of the situation, and explained that he had but to will the one word *"no"* to turn the scales that held his future in his favor. He stayed not only three months, but also the rest of the summer. In the fall he went back to his medical practice, a mentally and physically recuperated, able man. I heard nothing from him until about a week ago, when I received a letter from him stating that he has never returned to his old habits and now holds a position in the medical department of a large railroad company. This case shows the whole problem in a nutshell. If he had been allowed to go home shortly after his drugs and alcohol had been removed I feel convinced that he would have drifted back into his old ways. Consequently, he would not have been able to attend to his medical practice, nor could he have obtained the responsible position he now holds.

Case II.—Mrs. L. was sent to me by her family physician in June, 1907, suffering from the drink habit. She was a woman of some position and felt the disgrace very keenly. After our first talk, in which I incorporated the responsibilities of her social position, the duties to her husband (a man of prominence) and his friends, to her children, and to the unborn child she at that time carried, she gave up the drink habit of her own volition and promised never to drink again in her life. She was rapidly improving physically under my treatment, but was tiring of the unaccustomed life in an institution, and, as I was convinced I could fully rely upon her promise, I advised her to go to the moun-

tains for a few months. She stayed there until the late fall and returned home an entirely new woman. A few weeks ago I met the physician who had sent her to me, and he told me that she had never again shown the slightest desire for alcohol, that she was the picture of health and the pride of her family.

Case III.—Mr. D., a prominent lawyer, came to our sanatorium in 1900 to be treated for alcoholism. All liquor was taken away from him during the first week. He was astounded and rejoiced at the result; a moral victory we took advantage of to compare his present joyful feeling with the wretched life he had led for years. We pointed out that when he returned to business he could always feel as well as now. He could attend to his professional duties more capably, to the benefit of his clients and his own pocketbook, and that this could be accomplished by strenuously setting his will against all pernicious habits, and in no other way. Last winter, over ten years later, I accidentally met him and his wife at the door of a New York theater. He called me by name, and in the presence of his wife told me how well and successfully my method had worked.

These cases might be multiplied almost indefinitely, but those mentioned will, I think, suffice. A physician of my acquaintance had a series of ten cases of alcoholism in the city of Hartford, Conn., treated along the lines suggested in this paper. These patients have been under his supervision to some extent for part of five years and not one of them has returned to their old habit.

Another physician has a series of twenty-five cases who were under his care during the past ten years. He used moral suasion to a great extent in their treatment and all of these patients have remained free from the drink habit.

One side of this question which should not be overlooked is the fact that for many years the disease excuse has been used by the laity in covering up their debauchery and we often hear the remark, "the poor fellow, he cannot help it, he is diseased, his grandparents were drunkards." While we must admit a neurotic influence in many families, there is no special reason why morphine, cocaine, sexual perversion, and all forms of dissipation should not fill the void and they often do. People turning to these habits as a solace for their craving for something which will help them through their morbid periods. In order to look at this question from a layman's standpoint I recently interrogated the manager of a café, in which the largest daily bar business in New York City is supposed to be done. My question to him was, "do you think alcoholism is a disease?" He replied (I quote his words), "*no,* not by any means; it is a habit." He also said "many men who have spent all their money on rum until they are financially in bad straits decide suddenly to cut it out, and do so without any help, afterward making good in the business world. They come to me and tell me that they are through with the stuff for good. It is a common thing to see men who have been steady drinkers for years cut it off without any help whatsoever."

I have on file several letters from judges of the city courts in various cities of New England, and they claim good results in curing these cases through the medium of a probation officer. The following is one of these letters:

"I am glad to know that the medical profession is taking up the question of drunkards, but I hope they will not make him out always a diseased individual. Of course, it is true, I suppose, that in some cases drunkenness is a disease, but the large majority of the chaps I am after are able-bodied loafers who hang around saloons and deliberately get drunk for the avowed purpose of being sent to jail, where they find very comfortable quarters, and in most of our Connecticut jails very little work. For what may be called a dipsomaniac a hospital for drunkards would be all right. The average fellow needs little or no medical treatment and will recover if the supply of whiskey is cut off and a supply of work substituted. For the younger victim I would have the law so fixed that if he showed a capacity for a trade he might be transferred to the reformatory and there learn a trade which would make him for life self-supporting."

We little know what can be done with persons utterly hopeless and forlorn, broken down in body and spirit. Instill into them the necessary strength of will and the battle is won. True, it is impossible to replace tissue destroyed by organic change, but where excesses have not made too far inroads upon vital organs the result of such treatment is the complete mental and physical rejuvenation of alcoholic patients with power added to their will never again to weaken.

PERIRECTAL ABSCESS.

By CHARLES J. DRUECK, M.D.,

CHICAGO, ILL.

The rectum, as a hollow tube, is held lightly in place in the pelvis by the connective tissues and muscles at points, above, below, in front, and behind, but on either side it is in relation with loose areolar and fatty tissues which are abundantly supplied with blood vessels and lymphatics and which are easily and frequently infected or inflamed. There is a continual variation of blood pressure in these tissues depending upon the condition of the bladder and rectum, whether full or empty, and even on the position of the abdominal organs. These alterations also have a marked effect on the development of infections. By the process of osmosis and through abrasions on the rectal wall the microorganisms and their toxins pass into the surrounding tissues and lymphatics.

It is a common thing in making rectal examinations to find sensitive points on one side or other of the rectum when there is no apparent intrarectal lesion. Sometimes it is difficult to differentiate between muscular rigidity and tissue congestion. In still other instances the invasion is greater and the infection is diffuse or circumscribed and usually ends in abscess. This fatty areolar tissue is the least resistant of the body tissues. The fat globules apparently making the best nutrient media for the microorganisms (the colon and tubercle bacilli and the pyogenic cocci) and they soon fill the acini instead of the fat cells. The position within the pelvis at which the abscess develops depends upon the course taken by the chain or system of lymphatics involved. The lymphatics in the skin about the anus are called the inferior hemorrhoidal lymphatics and travel along the perineum to the inguinal glands or else back behind the sacrum. The deeper lymphatics, called the superior hemorrhoidal, pass through the ischiorectal space to the hypogastric ganglia and connect with vessels supplying the gluteal tissues. These deep lymphatics pass to the

sacral and vertebral glands. Infectious toxins gathered up by any of these systems may be followed along the chain. When the glands retain the poison and become inflamed passage along that particular chain is blocked, but as the networks anastomose freely, not only with other branches of the same system, but also with deeper systems, the infection may be carried along other channels. In this manner two or more distinct abscesses may develop. This intimate relationship of the various lymphatics explains the occasional development of abscesses quite a distance from the anus following a very simple operation. Tuttle, speaking of this, calls attention to the fact that injuries of the anal canal may be followed by abscess of the ischiorectal fossa or in the cutaneous tissues of the buttock, while injuries deep in the rectum are likely to be followed by abscess in the retrorectal space or deep in the thigh. Thus, regardless of its situation, the abscess is always secondary to some lesion of the mucous membrane of the rectum or of the perineal skin, even though the abrasion cannot be found at the time of examination. The infection from these parts in being carried off results in either a breaking down of a gland or thrombosis of the lymph canal and thus develops an abscess. Singularly, these abscesses develop most frequently in healthy, robust, active men. Quenu considers this a lymphangitis. Where an abscess has existed several days prior to evacuation, a certain amount of adenitis necessarily develops in the neighboring glands and these may subsequently give rise to other abscesses. Microorganisms in these glands may remain virulent indefinitely.

The location of the abscess determines somewhat the severity of the pain. Abscesses situated near the anus, where there is considerable loose, areolar tissue which is easily distended, are much less painful than those situated where the sphincters are firmly bound by muscles and fasciae. The sphincter is also excited and its spasm increases the pain. When the abscess develops above the sphincter it frequently ruptures into the rectum and may present no external appearance. Digital examination, however, will demonstrate a globular mass indurated or fluctuating according to the extent of development. Bimanual palpation with one finger in the rectum and counter pressure on the perineum will be of much value in early diagnosis. Abscesses that originate below the levator ani muscle, which forms the physiological roof of the lower pelvis, empty either into the rectum or upon the skin and are only rarely fatal, although they may cause severe local and even systemic disturbance. Perirectal abscesses may be single or multiple and, when more than one, may connect, usually behind the rectum through the space between the levator ani and the sphincters. Even when they develop on one side and have existed for several days or open spontaneously, a second abscess frequently follows on the opposite side. The abscess is honeycomb in character, the fat cells being displaced, but the connective tissue reticulum remains. When operating it is essential to break down these pockets as otherwise the contained pus will burrow and infect new areas. Infection may, however, be carried up through the fossæ on both sides and two abscesses develop from one source. The process usually goes on faster on one side than on the other and the corresponding abscess may appear several days before the other. Such abscesses may not communicate.

Symptoms.—As a rule these abscesses develop acutely and with constitutional reaction, which in some instances is very serious. Locally, there is a vague feeling of soreness within the rectum which increases gradually to a dull ache and later a throbbing pain. Externally, there may be no signs at all if the infection is deeply seated, but if near the surface the signs of abscess will be seen, such as red or violet discoloration and swelling. A finger introduced into the rectum and pressed out and down will usually appreciate a circumscribed mass of induration or fluctuation. Defecation is extremely painful and dysuria may occur. In aggravated cases the swelling, tension, edema and redness about the anus appear erysipelatous and microscopical examination of the blood and excretions is necessary to differentiate. Sometimes the inflammatory reaction not only surrounds the anus, but involves the scrotum, perineum and thighs, but such is an extreme case. When the abscess is opened the pus is thick and cream colored, unless there has been extravasation of blood, when it may be brownish, and a clot may be expelled en masse or as debris. Shreds of necrotic tissue are frequently seen in the pus and indicate a septicemic character of the infection. The odor is foul and gangrenous, even though the abscess does not communicate with the rectum. The gush of gas when the abscess is opened is due to the pent-up condition of the pus and does not come from within the rectum, but is the result of bacterial life within the abscess. When the abscess is opened, either spontaneously or by the knife the constitutional symptoms immediately subside and often within twenty-four hours will have disappeared, but unless drainage is complete another abscess will form and the whole chain of symptoms recur. This quite frequently is the case if all the compartments are not broken down during the operation.

Treatment.—Palliative treatment or therapeutic measures are a waste of time, and local applications have been discarded because, while they give temporary relief and may even retard the progress somewhat, yet they never abort or prevent suppuration. We must never wait for suppuration, but drain freely and at the earliest moment, whenever we find well-defined induration, unless we think the condition is syphilitic. The incision should be wide enough to expose the whole field, permit the operator to see what he is doing and allow free and easy drainage. This operative technic is that followed by all surgeons and I need not go into details, but I have to offer a few suggestions regarding the postoperative treatment.

After the abscess cavities have been emptied and cleansed there is sometimes little or no hemorrhage, and in such cases no internal dressings, such as packings or tubes, are indicated, but the wound edges are best left free. A large, loose, absorbent perineal dressing answers all of the requirements. Occasionally a diffuse oozing persists and the wound should then be douched with equal parts of hot water and alcohol to induce coagulation. Should there be distinct hemorrhage which cannot be controlled by torsion or ligature, then packing is, of course, indicated, and if packing is used it should be removed in six hours to be replaced only if bleeding recurs. After six hours all of the dressings should be removed and the wound thoroughly douched with at least one gallon of normal salt solution at about 100° F. The index finger is passed into the wound to separate the surfaces and act as a guide for the douche tip to the deep recesses of the

cavity. This douching is repeated every six hours until the discharge ceases or the wound is very shallow. The wound must then be dressed twice daily until healing is complete. Dressing these cases but one each day is wholly inadequate because the wound surfaces become glued together and the discharges are retained under pressure and that means burrowing in another direction. I have discarded drainage tubes and gauze packings because when tubes are fastened into the wound by stitching them to the skin edge, you will find it impossible to handle the patient for cleansing the wound without painfully dragging on the stitch, and the squirming and twisting of the patient makes douching very unsatisfactory. If the tube is not fastened to the skin but is held by straps or bandages it almost invariably slips to one side or other and becomes an obstruction instead of a drain. And unless the tube is removed at each dressing and thoroughly sterilized before reinserting it becomes a bed of infecting microorganisms and retards healing more than it assists. Gauze drains are supposed to act by capillary action like a wick and if the secretions were as thin as water or light oil the gauze might serve its purpose. But the flakes of pus and fibrin in the discharges soon become matted in the mesh of the gauze and the dried serum glazes over the surface until in a few hours the gauze drain is really a loose, slimy plug in the wound. How often have we all seen the pus roll out of a wound when the gauze plug that was supposed to drain it was removed. While tubes and gauze may drain a perirectal abscess very satisfactorily for the first few hours after they have been placed *in situ*, yet their utility is so short lived and beset with so many disadvantages that I have discarded everything of that sort and rely on thoroughly separating the wound edges with my finger, using it to explore the depths of the cavity and to guide the douch tip. In this way it is easily possible to prevent superficial adhesions forming pockets which predispose to new abscesses. Because there is no foreign substance retained in the wound the divided nerve ends soon are covered over and in a few days the wound may be dressed or manipulated without causing pain.

Any deviation from the old-established proceedings must accomplish something worth while to recommend its adoption by the profession. By avoiding tubes and gauze drains in these perirectal abscesses the after-treatment is much simplified. The patient is not kept in bed until the cavity granulates to a shallow ulcer, but on the contrary is encouraged to get on his feet and walk about just as soon as he is able. I have several times had patients step to the lavatory, instead of using the bed pan, within a few days after the operation. Although I allow my patient to walk about to help himself, answer the calls of nature and thus relieve the monotony and backache of a prolonged stay in bed, I very emphatically impress upon him the dangers of sitting down, because while our patient is prone the wound edges tend to gape and when he is on his feet the surfaces are perpendicular, so that drainage is complete, but as soon as he rests upon his ischial tuberosities the lower skin edges are crowded together and the discharges are dammed back into nooks and corners. I, therefore, admonish him that rest in bed is essential, but he may be up and about each day for a little exercise. This is an important matter because these individuals are usually in otherwise good health and are frequently active, robust men. The frequently repeated douches in large volume not only flush out the septic discharges as rapidly as they collect, but they serve another no less important service. By the time a perirectal abscess has reached the surgeon a widespread lymphangitis and cellulitis has filled the pelvis and both lymphatic and venous circulations are much impeded. The douche here depletes the tissue through the wound the same as does the vaginal douche in periuterine congestions. In order to thoroughly reach all parts of the wound cavity it is necessary to make a digital examination at each treatment and thus notice early any points of local tenderness or induration, or any pockets we have overlooked in the operation. Another prolific source of danger in the after-treatment is the lower intestinal canal. After the customary purging prior to the operation it is the practice of some to confine the bowels for several days that the wound may be spared and the possibility of further infection. This, I believe, is an error, because no matter how well cleansed the digestive canal may be it still contains myriads of microorganisms and toxins, and as stasis is the first step toward toxemia it must be very evident that given a patient with a septic process in the pelvis it is essential that a positive current be kept up from the tissues into the bowels. To accomplish this I give my patient sufficient catharsis to produce two to four loose evacuations each day as long as he is under my care. The autointoxication that otherwise occurs after a few days is thus absolutely prevented. By this method of treatment I save two or three weeks in the time of convalescence and the patient improves so rapidly in general health that he is anxious to get about his duties. But it is fatal to success to let him slip out from under observation too soon. No one will dress the wound as carefully and conscientiously as is needed except the operator and I hold my patient down until cicatrization is nearly complete. In closing let me say that I consider the liberal, hot douche frequently repeated, and the free catharsis, fully as important as the operation itself. These procedures cannot be carried out except the wound be dressed wide open, and after a thorough trial I am convinced this method is superior to any in which an artificial drain is employed.

599 East Forty-Sixth Street.

ADENOIDS IN SCHOOL CHILDREN.

By PERCY R. WOOD, M.D.,

MARSHALLTOWN, IOWA.

Life's activities follow lines of least resistance. Energy, ambition, noble impulse, and high ideals all succumb to pain and ill health and are frequently usurped by idleness and vice. Inability to apply themselves comfortably drives multitudes of children from school and thus reduces the intellectual and moral index of communal and national life.

Statistics of school children indicate that from 20 to 30 per cent. suffer from adenoids. The greater number of these display no symptoms sufficiently definite to attract general attention. Examination of 13,458 of Chicago's public school children showed that 5,826 or about 42 per cent. had either adenoids or eyestrain.

The lymphatic structure of Luschka's tonsil, its anatomical relation to the respiratory current, and its contiguity with similar tissue in the nasal walls as well as its sensitiveness in the presence of the lymphatic temperament so expose it to irritation and

infection that it often fails to escape permanent hypertrophy during the eruptive fevers of childhood. Therefore, a larger percentage than generally imagined possess some enlargement of this gland which, if permanent, becomes a menace to hearing. Blake holds these growths responsible for 88 per cent. of deafness and Dench believes that one-half of the pathological changes occurring in the tympanum result from adenoids. Sohier Bryant claims that 98 per cent. of chronic middle-ear disease originates here, while Diemont finds that engorged and hypertrophied turbinals usually result from adenoids and should be removed with them. However not 30 per cent. of adenoid children present well-developed characteristics, and while some are physically and mentally deficient from this cause these are exceptions. The majority display no prominent symptoms and so evade detection until audition has been permanently injured. The gland in this latter class is comparatively little enlarged, and excepting a fringe occasionally overhanging the choanæ or a few strands stretching from the posterior lips of the Eustachian orifice, the vault appears normal to the novice, although the finger will appreciate a bed of soft tissue encroaching upon the retronasal space and quite obliterating the bursa and Rosenmueller's fossæ. There is slight retraction of the alæ nasi, an almost imperceptible nasal twang can be detected in the voice, and these children find it impossible to breathe through the nose. The tympanic membrance may be slightly retracted and somewhat reddened near the umbo and the hearing power is reduced.

Hearing is the most important function threatened, so that its conservation should dominate the thought of all who remove these growths, rather than the simple disposition of an obstruction or a foreign body. Patients should never be dismissed after such operations without careful examination of the anterior and posterior nares and the Eustachian tube, and a test of the hearing function, for seldom at such times are all these structures free from disease. Furthermore, the faucial tonsil almost never hypertrophies without a participation in the process of the pharyngeal, both being sections of Waldeyer's ring. Examination of the vault is therefore imperative in cases of enlarged tonsils and of the turbinals as well, for these latter, being associate bodies and largely of like structure, invariably participate in these inflammatory processes and become hypertrophied and engorged. I see many whose tonsils alone or in conjunction with adenoids have been removed, who still suffered with progressing deafness and tinnitus, due either to inadequate removal of the adenoids, to the too frequent mistake of removing the tonsils without recognizing the presence of the former, to failure to consider the etiological significance of diseased turbinals, or lastly to want of after-treatment applied to the Eustachian tube. Such errors have been the means of causing many to pass into adult life to seek assistance for their hearing when too late.

Finally this hypertrophied mass, in untreated cases, becomes fibrous and dense and takes on a submerged aspect, and although seemingly of little significance still exerts a malign influence over the hearing. The error is frequently made of treating these elderly individuals for defective hearing without removing the cause. Solis Cohen reports finding adenoids in persons of 70 years of age. Rankin of Marseilles at 60. I find them with great frequency in middle-ear deafness and chronic throat affections regardless of age, and no case of deafness can hope for permanent relief while a vestige of this pathological tissue remains. Nonappreciation of these facts has rendered of no avail many a well-intended operation, and has frustrated earnest efforts to relieve cases of catarrhal deafness and tinnitus.

Exploratory Puncture of the Posterior Vaginal Cul-de-Sac.—J. L. Faure says that puncture of the posterior cul-de-sac of the vagina is of great value in some abdominal conditions, and should be made more often than it is made. In case of a collection of fluid in the cul-de-sac, such as a hematoma, it is desirable to know whether the collection of fluid is infected or not, since the nature of the operation to be done will be determined by whether it is simple blood or has been infected and become purulent. If infected it must be removed by way of the vagina; if uninfected laparotomy may be performed. The puncture may be done with a Pravaz syringe in the dorso-sacral position and is very simple.—*La Gynécologie.*

The Advantages of Modern Lithotrity.—G. Luys describes the advantages which the modern operation of lithotrity has over hypogastric section. One objection urged against the former has been that it is an operation in the dark. This objection may be disposed of by the statement that cystoscopy permits adequate inspection of the work accomplished by the lithotrite. In the hands of the skillful this operation is not a difficult one. The steps in the operation are as follows: 1. Dilatation of the urethra if is this narrow or stenosed. 2. Preparation of the bladder; if this has a capacity less than 150 grams, it should be treated previously by means of lavage and instillations of nitrate of silver. 3. The urine should be examined for glucose and albumin and particularly for its content in urea. 4. By means of the cystoscope it is necessary to determine the nature, size, and location of the calculus. 5. On the eve of the operation a sound should be passed into the urethra, and the patient should be given a purge. The operation comprises three steps: a, the crushing of the stone with the lithotrite; b, the evacuation of the fragments with a syringe or an aspirator; and c, the examination of the interior of the bladder with the cystoscope, to determine whether all the fragments have been removed. The contraindications of lithotrity are as follows: If the calculus is too large, exceeding 7 cm. in length, one may experience great difficulty in crushing it. If the stone is too hard even for a large lithotrite, one should not persist in the crushing operation, but should proceed to hypogastric section.—*La Clinique.*

Salvarsan in Obstetrics.—J. Lemeland has made a study of all the cases reported as treated with salvarsan during pregnancy, as to the effect on the mother and on the fetus. Up to date there have been 39 cases of treatment during pregnancy reported, but of these seven were reported with no detail. In the case of the women treated it is shown that the effect of the drug is the same as in other patients, abortion is not produced, the patient bears the drug well, and there is no intoxication of the fetus. The Wassermann reaction is affected in the mother just as in other cases, while in the child it disappears more slowly than in the adult. Of the infants there were 30 living and two dead. In the direct treatment of the infants with hereditary syphilis, out of 66 treated there were 45 cures and 21 deaths. In 18 cases the treatment was given to the infant through the mother. Here we find 6 successes and 12 failures, with 3 deaths. The drug does not have the effect by passing into the milk, but by the development of antitoxins in the blood of the mother which passes to the infant. Serum from persons treated with the drug was injected into one infant with improvement followed by relapse. Thus we see that in congenital syphilis the drug has beneficial and curative effects.—*L'Obstétrique.*

MISTAKES IN MEDICAL PRACTICE.

THAT an individual is taught by experience is another way of saying that he profits by the mistakes he makes. That medical practitioners are capable of making mistakes is a fact that furnishes a perennial topic of conversation for the laity who are usually shocked at the possibility of such an occurrence. This naturally accounts for the reticence which physicians display regarding their own shortcomings in this respect, which attitude is apparently counterbalanced by an undue willingness to discover the mistakes of others. One of the main causes of the unreliability of medical statistics is the paucity of the reports of failures as compared with the abundance of reports of successes. Such failures are inevitable in the efforts to further the progress of medical science; there can be no question that their value as recorded facts is equal to that of successes. Of greater value, however, than the reports of unsuccessful lines of treatment, would be the publication of the individual mistakes, whether of observation or of judgment, of which every practitioner accumulates a goodly store. Certainly such publication would be an inestimable boon to the younger men, who before they have the chance of feeling the sting of their own inevitable mistakes, may greatly profit by a perusal of those made by their older colleagues.

An illuminating philosophical analysis of the causes of mistakes in medical practice is presented in the Address in Medicine delivered by Byrom Bramwell at the recent meeting of the British Medical Association, and published in the *British Medical Journal* and the *Lancet*, July 29, 1911. The extensive experience of the Edinburgh clinician enables him to speak with authority on this subject and to illustrate his remarks with numerous examples from his own practice. At the outset he declares that it is not a question of who makes and who does not make mistakes; it is only a question of who makes the most mistakes and the biggest mistakes. Postmortem examinations reveal the frequency of these mistakes, which arise because of the extent and complexity of modern medicine and of the concrete problems with which the physician has to deal; the insufficiency of data; the difficulty in eliciting and observing the facts; the circumstance that one must frequently rely on the statements and observations of the patient or his friends, which statements are often inaccurate and misleading, and lastly because of the limitations of the human mind. There are bad mistakes, slight mistakes, mistakes of omission and those of commission, mistakes due to incomplete, inaccurate, or erroneous observation, and mistakes due to hasty or illogical conclusions.

Mistakes due to imperfect knowledge, to want of clinical experience, to erroneous observation, and to inability to observe correctly, are most common in the early years of one's practice. Bramwell illustrates this class of mistakes with the following examples: He had mistaken hemoptysis due to mitral stenosis for phthisis; and hemorrhagic smallpox for typhus fever; and he had failed to discover the cause of a fixed pain in the back in the pressure of an aortic aneurysm. It is pointed out in this connection that one must always give due weight to the patient's symptoms and complaints.

In the case of experienced practitioners, hurry, with its consequent incomplete examination of patients, and hasty conclusions are probably the most common causes of errors in diagnosis. Mistakes are frequently due to the fact that the information obtained from third parties is insufficient, inaccurate, and misleading. The importance is emphasized of verifying one's facts before giving an opinion. Mistakes due to erroneous deductions and illogical conclusions are very common. "Nor is this to be wondered at," says Bramwell, "when it is remembered that there is probably no faculty of the human mind which differs more in different individuals than the faculty of judgment—the power of seeing things in their correct proportion, the ability to weigh correctly all the facts of a case and to draw the correct and logical conclusion from them. Even those men in whom the judicial faculties are most highly cultivated often fail to draw the same conclusions from the same facts. How frequently we see the judges differing on points of law, and the opinions and decisions of the lower courts reversed in the Court of Appeal and in the House of Lords! Now, if this occurs in law, how much more likely is it to occur in medicine; for, in comparison with medicine, law may be almost regarded as a fixed science. Further, in medicine the facts on which our conclusions and opinions have to be based are, in many cases, very difficult to observe, and, in some cases, chiefly or entirely consist of the subjective sensations described by patients."

Mistakes in diagnosis frequently occur because either undue or insufficient importance is given to some symptom or physical sign which is present. Illustrations of this form of error are seen in the diagnosis of ulcer of the stomach when the gastric crises of tabes are present, and in overlooking the possibility of appendicitis as the underlying cause of hematemesis. Bramwell believes that there is a tendency to attach too much importance to some of the instrumental and other elaborate methods of diagnosis and to underestimate an all-around clinical experience and knowledge. Errors are often due to the fact that one's judgment is warped or biased

from some cause, such as anxiety or fear. For this reason the physician is incompetent to treat disease in himself or in members of his own family. Erroneous therapeutic conclusions, based on too limited a number of observations, are so common as to require no comment.

In concluding his address, Bramwell states that "the only way to avoid diagnostic mistakes is, *first*, to gather carefully and correctly the data—the facts on which the diagnosis has to be based—by exhaustive and accurate clinical observation and examination; *secondly*, after these data have been obtained, to weigh them impartially and judicially, taking all the facts into consideration, avoiding, so far as possible, preconceived opinions, giving due weight to the symptoms and sensations of the patient as well as to the physical signs; and, *thirdly*, to draw a logical and correct conclusion from the premises." This address deserves to be carefully read and digested by every practitioner, whether young or old.

MODERN TENDENCIES IN SURGERY.

One of the leading events at the recent meeting of the British Medical Association was the Address in Surgery by Professor Jordan Lloyd, surgeon to the Queen's Hospital of Birmingham (*British Medical Journal* and *Lancet*, July 29, 1911). Speaking from a wealth of surgical experience rarely surpassed in variety and extent, with the freshness of originality and the authority of a master, the orator was followed with close attention as he traversed this wide and well-trodden field, and indicated the conclusions of his independent judgment. He deplored the tendency to turn a surgical operation into a ritualistic function. In his view it needed but little ceremonial to make and keep one clean in body or in spirit; simplicity, sincerity and steadfastness being sufficient in both, and elaboration of ceremonial would but condone lack of dexterity or of resourcefulness. The advance in abdominal surgery had been gained only after a severe conflict with the elders, who asserted that the abdomen was a region into which the writs of ordinary surgical laws should not run, and in this combat Tait was the foremost protagonist.

With reference to kidney diseases that are amenable to surgical treatment, the speaker believed that most of these can be diagnosed by simple methods, by urinary investigation, by physical examination, by accurate history and finally by clinical common sense. It is only in exceptional cases that the cystoscope, the radiograph, and the ureteral catheter are wanted, but sometimes they may be wanted badly. Appendicitis was to be regarded as primarily due to mechanical obstruction of the appendical lumen, the appendix being essentially a part of the large intestine and subject to the same disturbances. If every case of appendicitis were operated on within twelve hours of its onset this disease would almost cease to be a mortal disorder. Twenty years ago appendicitis found no place in the Registrar-General's returns, whereas last year 432 cases were operated on at two Birmingham hospitals, and probably 40,000 cases of appendicitis occurred in England and Wales. The operative treatment of gastric disease was regarded by the speaker as the most striking example of modern surgical advance. Both suprapubic and perineal prostatectomy had their respective merits, the latter being preferable in the case of a slightly enlarged, tough organ in a stout patient.

The past three decades had beheld an enormous growth both in the extent and in the quality of hospital treatment. In 1872, when the speaker began his studies, 316 operations were performed in the two general hospitals of Birmingham; in 1910 the number was 4,472, although the service of beds had but slightly increased. Each surgeon was now doing more operative work than the united staffs of both hospitals had done thirty years ago. Probably 600,000 operations were performed in the public hospitals of the United Kingdom last year; these represented a huge amount of gratuitous work, the bulk of which was done by men with reputations already made, and the only public recognition was a perfunctory vote of thanks at an annual meeting of subscribers. The speaker believed that the time must come when most of this work would have to be paid for, presumably from public funds. Lastly, reference was made to the extravagant outlay on hospital construction and equipment. The craving to spend lavishly other people's money was a disease, and institutions might have to be erected for the persons so afflicted. Contrasting a great voluntary hospital with a modern municipal infirmary, the speaker pointed out that whereas the former cost $4,000 per bed for capital outlay and $10 per patient per week for maintenance, the latter cost $450 per bed and $3.62½ per week for each patient; and he believed that the sooner public hospitals became State supported, the better for patients, physicians, and the public alike.

The experience of English hospitals, judging from the above statement, would appear to be quite the opposite to that of American institutions, at any rate of some of the hospitals in New York City that are maintained by private organizations. These are doing the city's work at an expense much less than that which prevails in some of the city's own institutions.

Professor Lloyd's remarkable address touched upon some of the most fundamental problems in surgical practice and hospital management, and while some of the statements made will be certain to excite criticism and possibly controversy, nevertheless the oration as a whole points the way to surgical progress.

ESSENTIAL NARCOLEPSY; NARCOLEPTIC PETIT MAL.

That narcolepsy occurs in a form which is not only entirely independent of epilepsy and hysteria, but cannot even be brought into relationship with spasmophilia or with any form of neuropathic substratum, is a well-established fact. At a recent society meeting held at Breslau (*Berliner klinische Wochenschrift*, July 3) one case was reported in detail, while discussion brought out reference to two others. Aside from the paroxysms of the affection,

the most interesting feature was its complete nosological independence. While many nervous maladies present puzzling affinities with one or more other affections, the isolation of essential narcolepsy seems complete. All three cases occurred in young boys, but aside from the similarity of the clinical phenomena but little information is given concerning two of the cases. Bonhoeffer's case is given in detail. The boy was wholly normal, free from all evidences of degeneracy, psychopathy, and neuropathy, or of spasmophilia, and in particular it should be emphasized that no sleep disorders had been present. His ascendants and the other children in the family showed no anomalies of significance. The attacks bore some resemblance to epileptic petit mal, but the patient remained conscious and no depression, somnolence, or headache resulted. The extreme frequency of the attacks seemed characteristic, they amounting to over thirty a day at times. The child's walk was suddenly arrested, but he did not fall, even when his footing was hardly secure. He sometimes dropped objects held in the hand, but as a rule retained them. Occasionally his knees gave way, or he made a misstep. If the bladder was full a little urine might escape. There was never an aura or warning of any sort. Occasionally the patient could produce an attack artificially by making a sudden or violent movement. The seizures lasted but a few seconds, so that there was no opportunity for many tests. There was no history of fright or psychic trauma in this patient, but in the other boys the attacks began after a mild shock (collision with a bicycle; threatening action of a dog). Psychic excitement appeared to render the attacks a little worse. The seizures were absolutely refractory to bromides or any antihysterical remedies or procedures. Just before the earliest attack the patient showed a brief phase of depression, although his disposition was habitually cheerful. That a psychoneurosis should occur with absolutely no collateral evidence of nervousness is, of course, not to be expected. A latent taint, however slight, must be present. It is none the less true, however, that in these cases there was an absence of history and of stigmata pointing to psychopathy—something hardly conceivable of other psychoneuroses. The name narcolepsy seems poorly chosen for this affection, which indeed is very difficult to characterize in a word or two. Since the term was used originally to designate sudden attacks of somnolence in hysterical and other neurotic subjects, it would seem proper, if the condition under consideration is really to be conceived as narcolepsy, that it should at least be termed narcoleptic petit mal. Its marked resemblance to epileptic petit mal should sanction the use of such a term. Not only the sudden inhibition, but the pallor and pupillary change are common to both. The differences are, however, too striking to permit of confusion.

THE PARATYPHOID INFECTIONS.

Views as to what are generally known as the paratyphoid infections are somewhat vague. In most epidemics of typhoid fever there occur infections which are not of the true typhoid-fever type, that is, which do not react to the Widal test. These infections are of the *Bacillus paratyphosus* A or B class, but concerning these bacterial forms knowledge as yet is by no means accurate. As a rule such infections are lightly regarded by medical men, often diagnosed as intestinal grippe, and generally treated as of small account. T. A. Starkey, professor of hygiene at McGill University, some few years ago called attention to the prevalence, even preponderance, of typhoid-like infections in the epidemics of typhoid fever which have occurred not infrequently in Montreal and in other parts of the Province of Quebec. Starkey pointed out that during the epidemic of typhoid fever which prevailed in Montreal and vicinity in the winter and early spring of 1910 cases of typhoid-like infections were very numerous. At the recent meeting of the Canadian Medical Association, held in Montreal, a symposium on typhoid fever and water supplies took place in the section of preventive medicine. Starkey, who was chairman, again raised the question of the prevalence of typhoid-like infections in epidemics of enteric fever, and cited one epidemic which came under his observation in which the large majority of cases were those of typhoid-like infections. He further expressed the opinion that these infections were not looked upon in a sufficiently serious manner by physicians, and stated that he held the view that the typhoid-like infections should be considered under the general term enteric fever. With this view the members of the Canadian Medical Association present agreed.

In the *British Medical Journal,* June 3, 1911, is a letter from Col. R. H. Forth, R.A.M.C., relating to the same subject. Forth says there appears to be a tendency in Great Britain to apply the term "paratyphoid fever" to cases of infection by the microorganism known as *Bacillus paratyphosus* B, while there is a tendency to overlook the infection by the closely allied microorganism known as *Bacillus paratyphosus* A. Forth claims that there is a recognizable definite clinical entity caused by the latter bacillus. This clinical entity is a fever or pyrexia of the continued type, and because this fever is caused by the *Bacillus paratyphosus* A, Forth thinks to it should be applied the term paratyphoid fever. *Bacillus paratyphosus* B and *Bacillus suipestifer* do not really cause fever, he says, but explosive infections of the nature of an acute enteritis, commonly the outcome of what is called "food poisoning."

The Brainless Dog.

With improvements in technique, including anesthesia and asepsis, it has now become possible to maintain animals alive and in relative well being after removal or extensive modification of organs generally held to be of immediate vital significance. Pavloff's dogs which live for years in good health despite permanent gastric and esophageal fistulæ and stomach pouches, will at once suggest themselves to the reader in this connection, as well as animals which survive after wide removal of the stomach and intestine. Such survival may be aided by scientific feeding. The removal of the cerebral hemispheres in cold-blooded animals and certain

birds has long been practised in order to determine the significance of these structures to life, but our efforts in this direction in the higher animals were originally handicapped by the unfavorable results of the operation itself, due largely to the highly defective technique. At the Verein für innere Medizin und Kinderheilkunde of Berlin (*Münchener medizinische Wochenschrift,* June 27) Rothman exhibited a dog without a cerebrum which had survived first partial and then complete removal of the hemispheres since February, 1907. At that time the left hemisphere was removed, and about two years later its fellow. The animal was not a mere automaton, but presented the appearance of a normal dog, eating and running about. For a short time all functions were suspended, but it soon learned to walk, swallow, and lap milk. It can neither see, hear, nor smell in the full sense of the words, but is capable of sensorimotor acts, such as acoustic reflexes and snuffling. The sexual functions are abolished. The animal, a male, urinated at first in the manner of puppies and bitches, but soon made attempts to lift its leg during the act. There is marked defect in localizing all kinds of sensations—pain, pressure, touch, etc. A unique phenomenon appears to be spontaneous fits of rage, attended by baying. These are spoken of as impulsive, but they can also be induced by touching the animal. They can be arrested by gently scratching the animal's head, and they show a tendency to become less marked with time. This phenomenon may show that the irrational and purposeless barking of dogs, especially at night, is wholly unconnected with cerebration and is a mere low-level reflex.

A New Diagnostic Sign.

The external malleolar sign, as C. G. Craddock calls it, is an extension of one or more or all the toes, with or without spreading of them, when the external inframalleolar skin area is irritated. Craddock, who describes it in the *Interstate Medical Journal* for July, says it is diagnostic of organic disease in the spinocortical reflex paths. For several months he made examinations of the skin reflexes by irritation of the external inframalleolar area, and noted the following variations between the relations of external malleolar non-response and response: 1. In one case of left-sided cranial fracture, with no external malleolar response, there was for some days complete abolition of the right skin reflexes, with final return of the normal plantar, but never any malleolar response. 2. In a number of cases in which a response was obtained from the external malleolus normal response was obtained from the sole. 3. In a few cases, after persistence of external malleolar response and normal plantar response, plantar response became abnormal for a time, then disappeared, leaving the external malleolar response, which finally disappeared. 4. In other cases, with initial plantar and external malleolar response alike of extension, abnormal plantar response changed to normal plantar response, leaving malleolar response persistent. 5. In many cases in which plantar response was mixed, *i.e.* showing flexion and extension and varying strikingly with place or intensity of irritation and with voluntary jerks, external malleolar response removed any doubt of the nature of the plantar response. 6. In several cases of articular deformity limiting movements of the toes the absence or presence of external malleolar response was decisive for diagnosis. Craddock cites many cases which have come under his observation in order to show that irritation of the external inframalleolar area causes no reaction normally; that the external malleolar sign is usually present when the Babinski phenomenon is present; that it is often present when the Babinski phenomenon is absent; that it may come before, accompany the Babinski phenomenon, or outlast it; and finally, that its presence or absence is a great clinical aid in the interpretation of doubtful or occasional abnormal movements excited by irritation of the sole, and that it signifies disorder of an organic nature in the spinocortical reflex paths.

Carbohydrate Metabolism.

It is known or believed that a number of important organs are in some way actively concerned in the combustion of sugar—the liver, pancreas, muscles, suprarenal bodies, the central nervous system, etc. The claim made several years ago by Cohnheim that the pancreatic hormone could act only in association with some principle in the voluntary muscles was promptly disputed. The existence of so-called adrenalin diabetes was discovered, and while the mechanism is unknown, it has been ascertained that adrenalin and the pancreatic hormone are antagonists, the former producing glycosuria, or in other words interfering with sugar combustion, while the hormone promotes the latter. The two principles also behave antidotally to each other. At the recent meeting of the German Congress for Internal Medicine, Michaud read a paper on carbohydrate metabolism in dogs with an Eck's fistula (*Berliner klinische Wochenschrift,* June 5). When the liver is thereby eliminated no carbohydrate intolerance results. The animals eat grape sugar up to 150 grams without any increase in the normal percentage of sugar in the blood and without glycosuria. The pancreas is thus seen to be equal to the task of completely oxidizing the sugar. Adrenalin injections no longer produce glycosuria, showing that this substance normally produces the latter through some action upon the liver. It was admitted, however, that Eck's fistula does not absolutely cut out the liver from the circulation, even though this is practically the result.

Permanent Uncomplicated Astereognosis.

The highest interest is attached to injuries to the cerebral cortex in which with intact sensation and motion, and, in fact, all other cortical functions, the association of present sense impressions with the memory of past impressions is permanently disorganized. At a recent meeting of the Giessen Medical Society (*Deutsche medizinische Wochenschrift,* July 6) Hohlweg reported a case of trauma over the right parietal bone in a youth, the immediate effect of which was twenty-four hours of unconsciousness. It was said by bystanders that spasms of the left arm supervened at once upon the injury. These spasms persisted for fourteen days. The patient's cortical functions now became quite normal, save that he was unable to tell by the unassisted sense of touch the nature of objects held in the left hand. While tactile, thermal, and general sensibility were normal, the patient with the eyes closed was quite unable to distinguish with this hand between a watch chain, a piece of chalk, a matchbox, a key, etc. The case was, therefore, an example of pure astereognosis. The condition had persisted for five years unchanged.

News of the Week.

The Cholera Situation.—Reports come of a serious outbreak of cholera at Shanghai, China. The official cholera bulletin of Italy shows that the disease may be on the decrease in that country, there having been 1,039 cases with 380 deaths from August 1 to 5, and 781 cases with 294 deaths from August 5 to 10. Although there has been some alarm over suspected cases in Paris, the only point of real danger in France is Marseilles, where there were 16 deaths in the insane asylum in one day. The sanitary condition of other French ports is said to be satisfactory. The authorities of Vienna have been alarmed over the situation to the extent of prohibiting the importation or transit of any second-hand clothing or rags from Trieste, where 26 cases have been reported. While there have been no new cases in New York, vigilance has in no wise been relaxed. The disease has evidently been present for some time in Constantinople, as a despatch to *The Sun*, dated August 15, states that there were 113 cases there, with 64 deaths the day before.

Surgeon Injured in Ambulance Crash.—An Amsterdam avenue car in charge of an inexperienced motorman collided with an ambulance from the J. Hood Wright Hospital on August 12, very seriously injuring the surgeon, Dr. H. C. Cohen.

An Experiment in Caring for Employees.—The International Harvester Company is planning to install a scientific system of studying employees for evidences of incipient tuberculosis. At present the scheme is only in the experimental stage. The object is to find out what employees or number of employees are suffering from tuberculosis, and what remedies to adopt for their cure. If the plan is found to be practical an expert on tuberculosis will be stationed at each of the company's plants to render advice and assistance to those afflicted.

A Medal for Sir Patrick Manson.—It is proposed by a number of physicians especially interested in tropical medicine to raise by international subscription a fund for a gold medal to be presented to Sir Patrick Manson in recognition of his labors in behalf of this new branch of medicine. The medal will be in the form of a plaque 7 cm. (2.8 in.) long by 5 cm. (2 in.) wide, and will contain on one side a relief portrait of Sir Patrick, executed by Dr. Paul Richer of Paris; on the other a suitable inscription. Subscriptions may be sent to Dr. James Cantlie, 140 Harley street, London, or to MM. Anchin et Houzeau, Place de l'École de Médecine, Paris. Those who subscribe $5 will receive a copy of the medal in bronze, those who subscribe $10 will receive a silver copy. The American signers of the announcement are Drs. Calkins of New York, Novy of Ann Arbor, Stiles of Washington, Ward of Chicago, and Welch of Baltimore.

Bequests to Charity.—Among the fifty organizations and institutions that profited by the will of the late John Curley of Brooklyn are the following: Sisters of the Poor of St. Francis, $15,000; Hospital of the Holy Family of Brooklyn, $5,000; St. Mary's Hospital, $5,000; St. Catherine's Hospital Association, $10,000; the Little Sisters of the Poor, $2,500; the Seney Hospital, the Dominican Home, Brooklyn Bureau of Charities and the Long Island College Hospitals, each $1,000.

The will of Smith Ely, a former Mayor of New York, who died on July 1, leaves $1,000,000 to charitable institutions in and around New York. Among the bequests are the following: Fresh Air Home for Crippled Children at Sea Breeze, Coney Island, $50,000; West Side Day Nursery, $10,000; Orange Memorial Hospital at Orange, N. J., and the Overbrook Hospital at Summit, N. J., each $50,000, provided the sums left be used to endow in perpetuity as many beds in each of the institutions as the by-laws of the institution allow. The document also provides that, after all debts and legacies are paid, the Children's Aid Society and the New York Society for Improving the Condition of the Poor each receive $100,000, on condition that the sum named be made a special endowment fund, to be known as the Ambrose K. Ely Memorial.

Under will of the late Patrick Goodman St. Francis' Home for Chronic Incurables and St. Joseph's Home for Consumptives each receive $500; the Rosary Hill Home Cancer Hospital, $250.

By the will of the late Meyer Seidenbach of Philadelphia the sum of $1,000 is bequeathed to the Jewish Hospital and $500 to the German Hospital.

The Investigation at Quarantine.—Among the witnesses who appeared before Charles R. Bulger, the commissioner from Lake Ontario appointed by Governor Dix to hear complaints of the administration of the Health Office of the Port, have been Dr. William K. Polk, president of the New York Academy of Medicine and Dean of the Cornell Medical School; Dr. Simon Flexner, of the Rockefeller Institute for Medical Research; Dr. John W. Brannan, head of the Bellevue and the Allied Hospitals, and Dr. William P. Northrup, all of whom testified to the competency and efficiency of Dr. Alvah H. Doty, the Health Officer of the Port, and all of whom were more or less rudely heckled by a man in the employ of the *Jewish Morning Journal* who seems to be a valuable assistant to the commissioner.

The World's Opium Conference.—All the nations have agreed to the holding of an opium conference at The Hague on October 15. England held out for an agreement on the part of all the countries to submit statistics on opium, cocaine, and morphine, to which all have now acquiesced.

A New Hospital for New York City.—A charter for a Lutheran Hospital has recently been filed with the State Board of Charities, and $200,000 has been pledged toward the enterprise.

The American Association of Clinical Research announces that it will hold its third annual meeting on September 27 and 28, 1911, at 234 Berkeley street, Boston, Mass. Dr. Alvin Roy Peebles of Boulder, Col., is president of this association, and Dr. James Krauss of 419 Boylston street, Boston, is secretary.

Two Medical Societies Unite.—As a result of the meeting of the Southern Minnesota and the Minnesota Valley Medical Associations at Rochester on August 3, a new medical society embracing the greater part of southern Minnesota has been formed. One of the features of this meeting was the memoir of Dr. W. W. Mayo, by Dr. Charles Hill, a physician now in his eighty-fifth year, who was formerly associated with Dr. Mayo.

A New Hospital for Haverhill, Mass.—This city has voted to begin the erection of a contagious hospital which will cost $25,000, and has under consideration plans for a general hospital, to cost $100,000.

Tuberculosis Sanatorium for West Virginia.—

The State Board of Control has selected a site for a tuberculosis sanatorium, containing 550 acres, near Terra Alta. The Legislature at its last session appropriated $40,000 for the erection of a State sanatorium

Licenses to Practise Medicine in West Virginia.—The State Board of Health has issued certificates to 59 of the 70 applicants for license to practise medicine in West Virginia.

Mutton for Football Players.—Dr. D. W. Burbank of Leland Stanford University, in his search for a more nutritious proteid upon which to feed the football squad, has discovered that mutton contains a large proportion of proteid. He is fattening his own sheep, with which the bootball players of the university are to be fed this fall as an experiment.

The City Children's Hospital.—The following new appointments on the visiting staff of New York City's Children Hospitals and Schools have been made: Dr. Claude A. Frink, attending surgeon, and Dr. Cleaveland C. Kimball, M.D.

Dr. Harry S. Gradle has been elected Professor of Ophthalmology on the Faculty of the Chicago Eye, Ear, Nose, and Throat College.

Cholera in Italy.—Cholera is spreading in Italy and has extended to Genoa and Leghorn. The official report by the Italian government on the cholera situation shows that from July 27 to July 31, inclustive, there were throughout Italy a total of 802 cases and 319 deaths.

New Quarters for the New York Health Department.—The city has leased the Abingdon building at Centre and Walker Streets for ten years at an annual rental of $58,000 for the Board of Health. The department will move from its present quarters at Fifty-fifth Street and Sixth Avenue as soon as the Abingdon building is completed and will occupy the entire building which has a floor space of over 100,000 square feet.

Governor Dix Appoints Food Committee.—Governor Dix has appointed a committee consisting of eleven members, all of whom are to serve without compensation, which is authorized to inquire into the purity, prices, production, distribution, and consumption of foodstuffs and farm and dairy products and to recommend remedial legislation next year.

Medical Colleges Consolidate.—The trustees of the University of Nashville Medical School have given the new Medical Department of the University of Tennessee at Memphis all of the equipment of that school, its good-will, and the right to claim itself the successor of the Medical Department of the University of Nashville. Property valued at $75,000 has been secured by the University of Tennessee for the medical school.

Laboratory for the City of St. Paul.—A new laboratory to cost $40,000 will be added to the St. Paul city and county hospitals.

Sioux Valley Medical Association.—This association, which draws its members from four States, met at Sioux Falls on July 20. The election of officers resulted as follows: *President*, Dr. J. E. Garver, of Sioux City; *First Vice-President*, Dr. G. G. Cottam, Sioux Falls; *Second Vice-President*, Dr. C. O. Wright, Luverne; *Treasurer*, Dr. S. A. Brown of Sioux Falls; *Secretary*, Dr. G. S. Browning of Sioux City.

The Piedmont, Va., Medical Society.—The mont Medical Society, which held its regular quarterly meeting at Charlottesville, Va., on July 30, 1911, elected the following officers for the ensuing year: *President*, Dr. George W. Starke of Overton; *First Vice-President*, Dr. E. D. Davis of Standardsville; *Second Vice-President*, Dr. H. W. Porter of Louisa; *Secretary*, Dr. Frank C. Scott of Orange; and *Treasurer*, Dr. J. T. Walker of Barboursville.

Obituary Notes.—Dr. Rudolph Frederick Bauer died at Philadelphia on August 10 at the age of 50 years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1885, and from the medical department of the University of Pennsylvania in the class of 1894. He served for a time on the staff of Wills' Eye Hospital and in the ophthalmological department of the German Hospital. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. Francis A. Howe of Newburyport, Mass., a graduate of the Medical School of Harvard University 1854, a member of the American Medical Association and the Massachusetts Medical Society, died after a long illness, on July 28, aged 84 years.

Dr. Lewis C. Sampson of St. Joseph, Mo., a graduate of the Ensworth Medical College in 1900, died July 23, aged 37 years.

Dr. Harry H. Hughes of Jackson, Miss., a graduate of the Medical Department of Tulane University in 1892, died after a brief illness on July 22, aged 43 years.

Dr. Oscar A. T. Haruff of Pueblo, Col., a graduate of the University of Colorado in 1903, died July 26, aged 32.

Dr. Gordon Byron Meldrum of Buffalo, Wyoming, a graduate of the Denver and Gross College of Medicine in 1899, died in Omaha, Neb., following an operation for appendicition on July 7, aged 37 years.

Dr. John F. Carey of Meadow, Wyoming, a graduate of the Jefferson Medical College, Philadelphia in 1867, and a member of the Wyoming State and Laramie County medical societies, died in Cheyenne on July 26, aged 69 years.

Dr. Stephen Pierson of Morristown, N. J., a graduate of the College of Physicians and Surgeons, New York City, in 1869; a Civil War veteran, who served with General Hooker in the Fredericksburg campaign and later was with General Sherman in the march to the sea; member of the New Jersey State Board of Education; member of the American Medical Association and the New Jersey State Medical Society, died on August 10, aged 67 years.

Dr. John H. Crippen of Waterloo, Iowa, a graduate of Hahnemann Medical College and Hospital of Chicago in 1872, a member of the American Medical Association and the Iowa State Medical Society, died on August 3, aged 59 years.

Dr. Henry C. A. Kirchner of St. Louis, Mo., a graduate of Washington University in 1878, died August 6, aged 61 years.

Dr. John A. Warren of Greenville, Ill., a graduate of Eclectic Medical Institute of Cincinnati in 1873, member of the Medical Society of the State of Illinois, died on July 28, aged 75.

Dr. Charles Eddy of Brooklyn, a graduate of Bellevue Hospital Medical College in 1873, died on August 10, aged 62 years.

Dr. John Randolph Quinn of Brooklyn, N. Y., died of apoplexy at his home in that city on August 10. He was born in Bangor, Me., in 1847, and was graduated from the Long Island College Hospital in 1872.

Obituary.

FRANK PIERCE FOSTER, M.D.

NEW YORK.

Dr. Frank P. Foster died at the residence of his son-in-law, Professor J. C. Smallwood, in Chadwick, N. J., on Sunday, August 13, from cancer of the larynx, from which he had suffered for nearly three years. He was born in Concord, N. H., November 26, 1841, and was educated in the public schools of that town. After graduating from the Concord High School he attended lectures for a time at the Harvard Medical School, but later came to New York, receiving his degree from the College of Physicians and Surgeons in 1862. After an interneship of two years at the New York Hospital he became an acting assistant surgeon in the U. S. Army, and at the close of the Civil War established himself in general practice in this city. He at first showed a leaning toward dermatology, but later directed more attention to gynecology, although at no time did he regard himself in the light of any other than a general practitioner. Prior to 1870 vaccination was done almost wholly with humanized virus, either arm to arm or with scabs softened in water. Observing the dangers of this practice Dr. Foster urged the exclusive use of bovine virus and with the assistance of the officials of the New York Dispensary obtained the general adoption of that method.

It was as an editor, however, that Dr. Foster was most widely known. His early training in English and the humanities in the Concord High School gave to his mind a literary bent which soon led him into medical journalism, first as a contributor of original communications and editorial articles to the Medical Record and other journals and later as editor of the *New York Medical Journal*. He was the dean of American medical journalists, the death of Dr. Shrady in 1907 having left him in that position. He became editor of the *New York Medical Journal* in January, 1880, serving in that capacity for over 31 years—a record of professional editorial headship surpassed in this country only by Shrady, who was editor of the Medical Record for 38 years, and by Isaac Minis Hays, who was editor of the *American Journal of the Medical Sciences* for 59 years. Dr. Foster was also editor of the monumental "Encyclopædic Medical Dictionary," the preparation and publication of the four volumes of which occupied his spare time for twelve years, of the "Reference Handbook of Practical Therapeutics" in two volumes, of "Appleton's Medical Dictionary," published in 1904, and of the medical terms in the "Standard Dictionary." For several years he was librarian of the New York Hospital Library, until that institution was discontinued and its books were transferred to the library of the New York Academy of Medicine. He was a member of the New York Academy of Medicine, of the New York County and State Medical Societies, of the American Medical Association, of the American Medical Editors' Association, of the New York Gynecological Society, and of the New York Dermatological Society; of the latter he was one of the founders and had served terms as secretary and president.

Frank Foster was a man of high ideals, firm in his convictions but open-minded and charitable toward others whose views were not as his; a man of culture, well read in the classics, a French and German scholar, and a writer of pure English; somewhat reserved not readily making new acquaintances, but genial and cordial in his bearing toward all; a pleasant companion and an entertaining conversationalist; of tender heart and kind disposition—a gentleman.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent)

CONGRESSES, BRITISH MEDICAL ASSOCIATION, ROYAL SANITARY, CANCER RESEARCH.—HOSPITALS AND INSURANCE BILL DEPUTATION.—LUNACY.—OBITUARY.

London, July 28, 1911.

This has been a week for congresses and conferences of all sorts. At Birmingham the British Medical Association has held its meeting, but I may pass by that, as you have special reporters there to inform you of the proceedings. The Congress of the Royal Sanitary Institute—its twenty-sixth annual meeting—was opened under the presidency of Lord Dunleath. The Lord Lieutenant (Earl of Aberdeen) attended, and opened the health exhibition, in which were displayed all sorts of sanitary materials.

Lord Dunleath devoted his presidential address to the subject of consumption, of which he attributed the diminished death rate to a great extent to the improvements of sanitary conditions. No mercy, he said, should be shown to a local authority which did not provide the prime requirements of pure air and water. Of the sixty or seventy thousand deaths a year, at least twelve thousand were those of children, and the sufferers at the moment of speaking were probably over half a million. There were two sources of infection—the affected person and the tuberculous cow. To protect from the first notification should be universal. The Edinburgh plan was a model one, the tuberculosis dispensary for directing home treatment, the isolation hospital for advanced cases, and the sanatorium for early cases. He regarded it as certain that a large number of diseased cows contribute to the general milk supplies—many are actually suffering from tuberculous udders, and give out poisonous milk, which is mixed with that of other cows and sold in our towns and cities. The local sanitary authorities must have a free hand and supervise the supply at every stage. Education in matters of diet and improved housing conditions were also measures by which progress might be made, and to the Irish crusade against consumption, led by Lady Aberdeen, the president paid a tribute which was warmly endorsed by the conference.

In the section dealing with preventive medicine, Sir T. L. Brunton was to deliver an address, but he was detained by illness, and Professor Letts read it for him. He reviewed the progress made, and said plague, leprosy, and typhus had been practically banished, but another "horrid disease," smallpox, he feared was "only dormant," and if the proportion of unvaccinated persons in a community became high an epidemic might break out. He pointed out that the law of health is that an unprotected person coming within range of infection will probably take it; but a vaccinated one, or, better, a revaccinated one, is immune. He hoped consumption in a few years would become as rare as leprosy. He had observed a connection between tuberculosis and insanity, and to find

out how to abolish one and not increase the other the nature of that connection must be discovered. Of late years fresh air had been regarded as a panacea for every disease, and the zeal of nurses had thrown open windows without care of cold draughts, the result being sometimes pneumonia and death. Even in phthisis it was desirable not to fall from the frying pan into the fire. Before building sanatoria all over the country, it should be asked whether the money might not be better spent. He thought more could be done for the health of the country by health visitors attached to hospitals and dispensaries, and in country districts under the medical officers of health.

The Lord Mayor of Belfast presided over a meeting of municipal representatives of sanitation, Sir William Byers over the section on the hygiene of childhood, at which Dr. Lindsay advocated the appointment of a minister of public health, and Lord Aberdeen spoke of the low infantile mortality in rural Ireland, for which he asserted Ireland might well be proud of her motherhood.

Yesterday at this congress the "State endowment of motherhood" was advocated by Dr. Eric Pritchard, who held that this was not so Utopian or extravagant as it might seem to some at first sight, for it was not easy to find any fundamental distinction between organized endowment of motherhood by the State and individual efforts for mother and child, such as lying-in institutions, nurseries, crêches, free meals, etc.

At the same meeting Dr. J. McCaw read a paper on measles in relation to child mortality and advocated notification. He was amazed that parents looked upon measles as trivial, as it killed more children than all other eruptive fevers combined.

A conference of medical officers was held at the same time, presided over by Sir C. Cameron. At this also compulsory notification was urged by Dr. Young, M. O. H. for Cheshire.

At the meeting of the Cancer Research Fund, briefly recorded last week, Dr. Bashford"s report showed that many disquieting statements were not correct. Parts of the body where increase appears must be considered in relation to other parts. Transference from the secondary to primary sites is illustrated by the relation revealed between cancer of liver, gall bladder, and alimentary tract. Increase in the breast in women and the tongue in man requires further study. The curve of incidence may differ for different organs. Progressive increase up to highest age-periods is characteristic of the face, lip, mouth, bladder, urethra, and breast only. Other organs show diminution in the highest age periods, but it is not determined how far this may be due to other causes of death being assigned in internal cancer of the aged. Variation in accordance with changes of certain customs must be admitted, especially such as cause local irritation.

But irritation as a causative factor is only to be admitted for certain forms in particular regions. Different animals and different tissues in them may have special irritants which should be studied. In man we must study this statistically. As to heredity Dr. Bashford warned against needless alarm, or the awakening of pessimistic anticipations of the outlook on future efforts to cope with the disease. It was impossible to explain the liability to transmission, but certainly it did not consist in the inheritance of a soil more suitable for the growth of cancer in general. It was not inheritance in that way, as shown by the fact that implantation in mice of a cancerous stock is not more successful than in other mice. Further, inheritance was only one factor, for in mice of the laboratory other chronic changes in the mammæ are frequent.

Sir Wm. Church, in moving the report, remarked that it was certain every tumor was genetically related to the animal in which it arose. The genesis and growth of cancer must be separately investigated. Variations in cultivated growths suggested similar variations in natural conditions and gave evidence that the cancer cell was a modification of the normal cell. Many experiments had been made in continuance of the work done on immunity but had given no evidence of power to produce it. Other investigators had described methods of obtaining immunity by sera and vaccines and some had been tried in this laboratory and as yet without success.

Sir H. Morris gave a warning as to the expenditure and said other bodies had rendered assistance to the Imperial Fund. He was glad to say the Walker prize for the best original work done during the past five years in any country in advancing the knowledge of cancer had been awarded to Dr. Bashford.

Mr. Lloyd George has received a deputation representing the various bodies concerned in the support of hospitals. Sir. A. Haworth, introducing the deputation, said it represented twenty hospitals which they felt would be injured by the Insurance Bill. Sir W. Corbett said at his hospital over £4,000 came yearly from the working classes' penny collections. Before the bill was proposed the collectors of Manchester Infirmary brought in about £18 per week. Since the bill was introduced the amount had sunk to £7. Mr. Holland said of the 222,000 outpatients of the London Hospital one-third would be affected. The Chancellor put off the deputation, as he did former ones, with statements which had little connection with the representations—such as that he had confidence in the common sense of his countrymen, doctors had often complained that hospitals injured them, he would like to know what would become of the millions from the Treasury, for he had not heard any one confess to getting some of it. He conceded the case of sick nurses on condition that the hospital paid their wages during sickness and provided medical aid. He has since placed on the paper a notice of the amendment he proposes to effect this.

The sixty-fifth annual report of the Commissioners in Lunacy was issued yesterday. It appears that in January this year there were 2,604 more certified cases than in the same month last year.

Dr. H. T. Bulstrode, Medical Inspector to the Local Government Board, has died suddenly. He visited Aldershot on official business on the 20th inst. and the next morning was found dead in his bed. The many reports he had to issue were invariably as able as the questions considered were important. That on pneumonic plague of last year is the most recent. He was President of the Epidemiological Section of the R. S. M. and Chairman of the Board of Hygiene in London University and held other honorary appointments.

Dr. John Beddoe, F.R.S., the distinguished anthropologist, died on the 19th inst. æt. 84. He served on the civil hospital staff in the Crimea. His "Races of Britain" will be known to you as an important work, and no doubt also some of his other works. He was M.D. Edin., 1853, F.R.C.P., 1873 and in 1891 Edinburgh made him LL.D.

Observations Regarding the Relative Frequency of the Different Diseases Prevalent in Boston and Its Vicinity. R. C. Cabot.
Prostatic Concretions and Calculi. F. B. Lund.
Remarks on the Classification of Diabetes. F. W. White.
The Result of Tonsillectomy. O. A. Lothrop.
A Report of Two Cases of Pneumococcus Meningitis. J. R. Wiseman.
Abdominal Pain from Antero-Posterior Curvature. M. H. Rogers.
Anterior Dislocation of the Hip. G. H. Monks.

Relative Frequency of Diseases in Boston and Its Vicinity.—R. C. Cabot concludes that in a hospital population of about 8,000 males over eighteen years old, all of whom were carefully questioned, 35 per cent. gave a history of gonorrhea, and 11 per cent. a history of syphilis, at some period of their lives. These histories and the resulting percentages are believed to represent approximately the truth about an average sample of Boston's adult males. The Americans, Irish, English, and Italians have about the same amount of both these venereal diseases. The Jews have about one-third as much syphilis and one-half as much gonorrhea as the other races. The history of an excessive consumption of alcohol was obtained in 32 per cent. of 8,356 patients questioned. The Jews show the smallest amount of alcoholism,—the "Americans" the highest percentage of total abstainers. About one-fourth of all the 7,186 adult males who were questioned gave a history of using an excess of tobacco. The Italians appear to use rather less than the other races but the racial differences are less marked as regards tobacco than as regards alcohol and venereal disease. The statistics relating to alcohol and tobacco are regarded as an indication of the habits of a fair sample of Boston's population. Acute nephritis, chlorosis, and sunstroke would appear (on the face of the records) to be decreasing. The decrease is shown by analysis, however, to be in all probability fallacious. Pyogenic infections are more than twice as numerous as any other known infection (tuberculosis included). Three Boston hospitals treated 6,892 cases of syphilis and only 4,819 of gonorrhea in the years 1903-1910 inclusive.

Prostatic Concretions and Calculi.—T. B. Lund on the basis of three cases which he reports states that prostatic concretions are frequently associated with infiltration of the prostate, which makes a small, fibrous organ feel larger than it really is by rectal examination and may lead to the suspicion of malignant disease. In removing large calculi from the prostate one should remember that they are surrounded by pus and inflammatory tissue and that special care must be taken to avoid injury to the rectum, the wall of which may be just right to perforate at the time of the operation.

The Classification of Diabetes.—F. W. White states that the "carbohydrate balance" in grams is one of the simplest and clearest guides in classifying diabetes, in comparing different cases, and in comparing stages in the progress of a single case. The "carbohydrate balance" is the difference between the amount of carbohydrate eaten and that lost in the urine; positive, if more is eaten than lost; negative, if more is lost than eaten. For example, if a patient eats 60 grams of carbohydrate and passes 30 in the urine, he has a positive balance of 30 grams; if he eats no carbohydrate and passes 30 grams, he has a negative balance of 30 grams.

The Results of Tonsillectomy.—O. A. Lothrop presents an analysis of sixty-one cases of enlarged tonsils operated upon by enucleation. In 91 per cent. there resulted decided improvement in breathing; in only 16 per cent. did the patient afterwards experience an attack of sore throat; in 10 per cent. dryness of the throat was afterwards complained of by the patient, and in 10 per cent. there was some injury to the upper part of one or both posterior pillars, but no impairment of voice thereby. Of 1,700 tonsillectomies performed in three years there were no fatalities from hemorrhage. The last was of any consequence in only two cases.

Pneumococcus Meningitis.—J. R. Wiseman reports two cases of this condition. He notes that the course of the disease is usually more rapid than that of any other form of meningitis, while treatment is of little avail.

Abdominal Pain from Spinal Curvatures.—M. H. Rogers reports two cases which illustrate the influence of antero-posterior curvature of the spine in the causation of abdominal pain.

Anterior Dislocation of the Hip.—G. H. Monks reports a case of this condition.

Relation of the Tonsil Operation to the Soft Palate and Voice. G. Hudson-Makuen.
Reflex Affections of the Tonsil. R. B. Faulkner.
The Renal Function in Surgery with Particular Reference to Kidney Surgery. L. E. Schmidt.
Some Cases of Optic Neuritis, Benefited by Operation upon the Spenoidal Sinus and Posterior Ethmoidal Cells. H. Smith.
Diagnosis of Brain Tumors. J. E. Burns.
The Diagnosis of Incipient Pulmonary Tuberculosis. B. S. Horowicz.
Use and Abuse of Coffee. R. E. Coughlin.
Hysteria in a Girl of Seven Years. G. H. Nofer.

Tonsil, Soft Palate, and Voice.—G. Hudson-Makuen states that normal tonsils are in no way prejudicial to phonation, but, on the contrary, they may be helpful both in directing the action of the neighboring muscles and in modifying the resonance of the oral cavity. Hypertrophied tonsils, on the other hand, are distinctly prejudicial to phonation, because they interfere with the action of the muscles, they deflect the vibrating column of breath, and impair the normal resonance of the oral cavity. Degenerate tonsils are prejudicial to phonation primarily because they are prejudicial to health, and, secondly, because they interfere with the action of important vocal organs, by setting up a catarrhal condition in the oropharynx, which results in hypertrophy of the faucial pillars, the plica, and the capsule, and in numerous inflammatory adhesions binding all these parts together in one conglomerate mass. The tonsil that requires removal is always prejudicial to vocal excellence; but to do a little good in an operation one should take heed lest he do a great harm. To do a satisfactory tonsil operation is often quite as difficult as to do any other operation in the region of the throat, nose, or ear, and it requires quite as much skill The tonsil operation, therefore, is the one of all others that should be done by the specialist, and it should be done with great care and deliberation. The popular belief that the removal of tonsils is injurious to the voice is well founded, and it is due in large measure to careless or bad surgery.

Reflex Affections of the Tonsil.—R. B. Faulkner states that the faucial tonsils may provoke reflex neuroses in other organs, but they should be awarded much less of the credit which they now receive for provoking reflex diseases; and they should receive undoubtedly some credit which they do not now receive for being affected by diseases reflected from a distant part.

Functional Tests in Renal Surgery.—L. E. Schmidt discusses the value of the various functional tests in the early diagnosis of various surgical diseases of the kidney.

Optic Neuritis.—H. Smith reports three cases of optic neuritis benefited by operation upon the sphenoidal sinus and posterior ethmoidal cells.

Diagnosis of Brain Tumors.—J. E. Burns discusses this subject in connection with the report of a case of brain cyst.

Diagnosis of Tuberculosis.—B. S. Horowicz deals with the early diagnosis of pulmonary tuberculosis.

Use and Abuse of Coffee.—R. E. Coughlin concludes

that coffee may be used in moderation except by nervous patients and by children. The therapeutic value of coffee should not be lost sight of, particularly in shock and vomiting after operations or hemorrhage, when it is best given in dram doses, without milk or sugar, every fifteen minutes. The relation of coffee-drinking to functional heart cases is alluded to. In patients with arterial changes the use of coffee should be prohibited.

Hysteria.—G. H. Nofer reports a case of this condition in a girl of seven years.

Journal of the American Medical Association.

Medical Botanists.—H. A. Kelly presents an account of many of the medical botanists of the early days in this country.

Gall-Bladder Surgery.—By E. M. Stanton. See MEDICAL RECORD, July 8, page 99.

Factors Hostile to Success in Gall-Bladder Surgery.—By B. B. Davis. See MEDICAL RECORD, July 8, page 99.

Mercuric Chloride Poisoning.—J. M. Mabbott reports a fatal case of this condition resulting from the administration to a patient seven days after delivery of a vaginal douche of two quarts of a 1 to 4,000 solution of bichloride of mercury.

Goiter Among the Insane.—A. Werelius and C. G. Rydin state that patients with dementia precox present the greatest percentage of goiters and also the greatest number of insane. As the catatonic form of dementia precox has been considered due to thyroid disturbance, one should look for the greatest number of goiters in this type. In fact, however, the authors found that hebephrenic forms had 93 per cent. of the goiters. Next to dementia precox came involutional melancholia and, next to it, the paranoiac state.

Tetany in Adults.—H. C. Moffitt reports six cases of this condition.

Prostatectomy.—E. S. Judd presents a review of 542 cases of prostatectomy performed at the St. Mary's Hospital. As a rule, the Rochester surgeons do not consider it advisable, if the symptoms are slight and only two or three ounces of residual urine are found, to operate. Within the last five years they have used the cystoscope to great advantage in 95 per cent. of the cases in determining the presence of stone and selecting the type of operation. The perineal operation is the one ordinarily chosen, but the cystoscope may show conditions calling for a suprapubic operation. The mortality is not especially affected by the type of procedure.

Shortening of an Ocular Muscle by Tucking.—H. W. Woodruff describes a tucking operation that he has devised, asserting that it is safe and effective, devoid of permanent noticeable deformity, and easy to perform under local anesthesia in any one over twelve years of age.

Ocular Conjugate and Fusion Brain Centers.—G. C. Savage presents his views as to the brain centers of the ocular muscles as modified by recent studies.

Changes in Refraction.—W. Zentmayer presents the following conclusions: Ametropia tends to change in degree even when the error is carefully and repeatedly corrected and the glasses are worn constantly. Almost every conceivable change may occur. The tendency is in the direction of an increase in the static refraction with an increase in the astigmatism. In compound hyperopic astigmatism the most frequent change is a decrease of the hyperopia with an increase in the astigmatism. In compound myopic astigmatism the most frequent change is an increase in the myopia with an increase in the astigmatism. There is no greater tendency for compound myopic astigmatism to change than there is for compound hyperopic astigmatism to change. Simple myopia (rare) is never a stable condition; it almost invariably increases in amount. Simple myopic astigmatism is the least, and simple hyperopic astigmatism the next least stable of astigmatic errors. Simple hyperopia sometimes remains constant, but is subject to undergo both an increase and a decrease. In compound astigmatism the static refraction may change without a change taking place in the astigmatism and *vice versa*. In mixed astigmatism the myopic meridian most frequently changes and shows an increase, although an increase of the hyperopic meridian with a decrease in the myopic meridian in the same eye probably occurs with the most frequency. Astigmatism is often acquired in hyperopic eyes, and as frequently in the third as in the fifth decade. Before the forty-fifth year the axis of the acquired astigmatism is as frequently with as against the rule, but after the forty-fifth year it is against the rule in 85 per cent. of patients. The total astigmatism may be lost, probably in any decade, but more commonly in the later decades, and at this time probably represents a transitional stage to an astigmatism against the rule. A change in the axis of astigmatism occurs in about 50 per cent. of the cases. The changes in the refraction occur with most frequency in the period of from twenty to forty-five years. After the forty-fifth year changes in the amount of hyperopia in compound hyperopic astigmatism occur much more frequently than do similar changes in compound myopic astigmatism. There is no greater tendency toward an increase in hyperopia between the fifty-fifth and sixty-fifth years than between the forty-fifth and fifty-fifth years.

Alcohol and the Wassermann Reaction.—C. F. Craig and H. J. Nichols state that no dependence can be placed on a negative Wassermann reaction in individuals who have, within twenty-four hours of the collection of blood, ingested considerable amounts of alcohol, while in some instances the drug may render the reaction negative for as long as three days.

Experimental Measles.—J. Goldberger and J. F. Anderson state that their experiments on monkeys clearly indicate that the mixed buccal and nasal secretions are certainly infective at the time of the first appearance of the eruption and again forty-eight hours later, and that the infective virus was susceptible of transfer from monkey to monkey by blood inoculation.

Vaccination.—H. W. Knight reports a series of cases illustrating the protective value of vaccination against variola.

Sodium Cacodylate.—S. L. Dawes reports the beneficial effects of this drug in the anemias of long standing, in pernicious anemia, in the neuroses accompanying anemia, in neuralgias and gastralgias, and in certain types of malaria. He believes that the drug is of little or no value in syphilis.

Sporotrichosis.—W. B. Steward reports a case of this condition.

Mistakes.—By B. Bramwell. See page 380.

Address in Surgery.—By J. Lloyd. See page 381.

The Extraction of Cataract.—H. L. Eason believes that no single operation can be adopted for all cases as a matter of routine. In selected cases a simple extraction without iridectomy is the best. In cases where there is likely to be much soft material removal of the anterior lens capsule with forceps will give good results, and in skilled hands the older methods of extraction of cataract are quite as efficient as, and probably safer than, extraction in the capsule.

The Appendix and the Adnexa.—H. Macnaughton Jones states that the appendix should be examined in every case of celiotomy for adnexal disease. This applies equally to the left adnexa as to the right. When the abdomen is opened for a grave appendical trouble the adnexa should be examined. The appendix should be removed in every instance where any abnormality or disease is found or if it be of unusual length, also if from the character of the operation there is a probability of further adhesions forming which may involve the appendix. The severity of the operation, however, will always have to be taken into account, and the influence its prolongation may have in lessening the chances of the patient's recovery.

Rubella or Measles?—D. W. C. Hood states that under the genus measles he would class rubella, coming before one, as it undoubtedly does, under many forms, and until the bacteriologist supplies more definite information he will continue to believe that the balance of clinical evidence is in favor of German measles being only a variety of the common type.

Ovariotomy and Cesarean Section.—H. B. Mylvaganam reports the case of a patient in whom both of these operations were successfully performed at the same sitting.

Acute Mercurial Poisoning.—A. W. Burton reports a fatal case of this condition, following the ingestion of 744 grains of corrosive sublimate in the form of soluble tablets.

Berliner klinische Wochenschrift.

July 17 and 24, 1911.

Differential Diagnosis Between Benign and Malignant Hourglass Stomach.—Kretschmer reduces this entire subject to two postulates: 1. In the malign form there arises an extended defect which is horizontal-vertical in the shadow; while in the benign this defect is a more or less horizontal construction. 11. It is more essential for the benign form that the upper sac empties into the lower; while in the malignant form both pouches are filled either in the same degree, or at first the pouch having the deepest level fills at that point.

Pulmonary Embolism.—Ritzmann writes at length on this subject with especial reference to Trendelenburg's operation. In regard to the frequency of the accident 55 cases were found in 6,000 autopsies. It is understood that the emboli were of the main branch. All patients were over 30 years of age, and most were between 50 and 70. There were as many females as males. The causes were various—vitium cordis, myodegeneration, arteriosclerosis, anemia and cachexia, conditions causing phlebitis, injuries, and operations. No affection stood out in preponderance as a cause, but nearly all the affections were related to vascular disease of some sort. The author has been able to diagnosticate 6 cases during life. In 29 other cases seen before death embolus was not recognized. Death was sudden, and in some cases it followed operation. At other times the sudden death would occur in advanced or terminal stages of diseases of the cardiovascular system. We may make two groups, viz., the diagnosticated and undiagnosticated. In all of the former death soon followed the diagnosis. In but one would there have been a chance for operation. The history of the undiagnosticated cases shows that in many of them, had a diagnosis been made, there would have been room for operation. Cases sometimes occur, therefore, in which, while the general condition is fairly good, the embolic formation cannot be overlooked; yet it is in these very cases that death rapidly ensues. Even with heart remedies death may result in twenty minutes. Most patients tend to survive for from half an hour to 48 hours and these cases tend to present diagnostic insuperabilities. In the combined material the chances for a successful operation are almost *nil*. Despite the slight prospect of obtaining operative cures of this affection surgeons should not forget that at least three have reported successes and the possibility should never be forgotten.

The Duodenal Tube.—Gross of New York claims that he suggested this instrument in 1894—a thin gastric tube which if slightly modified could be made to serve as a duodenal tube. His actual instrument was not described until 1910. By its use he has studied extensively hyperchlorhydria in reference to compensatory or other secondary alterations in duodenal secretions. Trypsin was evidently killed as long as the gastric chyme entered the duodenum in large amounts. As the tube has an air bulb attached it is possible to pump out much of the chyme. Simple insufflation through the instrument is sufficient to excite the duodenal secretion. A solution of magnesium sulphate (4:150) thrown into the duodenum causes prompt defecation. The author has obtained the normal duodenal secretion of thirty subjects, obtaining an average of an ounce from each. It was clear, strongly alkaline, and contained the three enzymes in every case.

Cultivation of Tissues Outside the Organism.—Carrel has recently demonstrated this subject at Professor Bier's clinic, Berlin. He was led to investigate the latter some years ago through a study of cicatrization *in situ*. In 1907 Harrison had shown that the central nervous system of a frog embryo will put forth nerve fibers when immersed in coagulable lymph. Burrows amplified this class of experiment and secured results of the same sort from a variety of tissues. The culture of tissue in general *in vitro* has now become a common practice and this cultivation has opened a new department in biology. Both epithelium and connective tissue proliferate and karyokinesis occurs freely. The life of cultures can be extended through several generations. For culture material natural blood plasma, ovserum, and Ringer's solution are used. It is immaterial whether the plasma comes from a homologous or heterologous source as far as the individual is concerned, but the latter must represent the same species as that from which the cells proceed. The concentration of the culture fluids was tested and this was found to have much effect on the rapidity of growth, so that the plasma component *per se* is probably much less important than the molecular concentration of the culture fluid, and may come to be shown as unessential. The immediate practical application of the subject lies first in the direction of repair of wounds.

Elimination of Salvarsan. — Frenkel-Heiden and Navassart write provisionally on this subject without seemingly increasing our knowledge greatly. The elimination by the urine is first considered. When the drug is injected beneath the skin or into the muscles over a prolonged period it requires months for its full elimination. This means that arsenic is indefinitely stored in the tissues, and it appears that not all of this stored arsenic is eliminated. Thus while the kidney stops excreting it at a given period—say three weeks—the drug remains for months in the kidney, and its elimination is so minimal that even the most delicate tests fail to show it in the urine. When given by the intravenous method the drug is known to be excreted somewhat more promptly. Of much interest is the fact that at least as much arsenic escapes by the intestine as by the kidney. In some cases elimination by the intestine is much greater in proportion. But little is known of salvarsan in this connection, but it is commonly known that arsenic, however administered, is expelled in part by the feces.

Urogenital Apparatus in Scleroderma.—It is now known, as Ehrenberg states, that scleroderma is a general disease and moreover one which is able to attack any tissue or organ in the body. The name is, of course, a misnomer. In addition to all the skeletal and locomotor apparatus it may attack the viscera and mucosæ, the latter more infrequently than any other set of tissues. Still the skin bears the chief brunt of the disease. In a severe case cited by the author the mucosa of the mouth and throat was attacked as well as the vulva (the lesions resembling kraurosis vulvæ), the vagina, the vesical mucosa, and one ureter. The bladder and vagina were atrophied and retracted. The etiology here as elsewhere was quite obscure, and treatment was of no avail. The author once saw a case develop in pregnancy in a goitrous woman, but in the present patient the thyroid was normal. Since kraurosis vulvæ is also known as a unique affection the thought might impose itself that it is a local type of scleroderma. But despite the superficial resemblance the histological picture is quite different.

Tracheopathica Osteoplastica.—Haga of Tokio reports the forty-third recorded case of this affection, which represents a bony and cartilaginous deposit in the tracheal mucosa, his article constituting a complete monograph on the subject. The lesion is to be conceived as a neoplasm having no relation whatever to the normal tracheal rings. This is certain at least for the author's and other cases carefully studied. Virchow claimed that the normal cartilage constituted a mother structure from which the tumor proliferated and then separated.

Münchener medizinische Wochenschrift.

July 25, 1911.

Thyreoses.—Krecke attempts a classification of these affections in a serial article. He divides them into (*a*) thyreoses with preponderant cardiac disturbance, comprising the so-called goiter heart; (*b*) those with predominance of nerve disturbance; (*c*) those with marked involvement of nutrition, and finally the so-called iodine Graves' disease and conditions which resemble it. The heart thyreoses are not entirely synonymous with what we call Graves' disease. Rather is the goiter heart a syndrome *per se*. We get Graves' disease with normal heart. There is also a mechanical type of goiter heart which has nothing to do with the ordinary or toxic type. There may also be a factitious association of a thyreosis and a cardiac disturbance. In true thyreosis with cardiac expression there is no difficulty in diagnosis. We invariably find tachycardia, with or without secondary hypertrophy. A particular clinical variety appears at puberty, chiefly in girls. These often suffer from pseudo-chlorosis. The involvement of other organs need not be touched on here. It is often very difficult to differentiate the toxic thyroid heart from an organic lesion.

Prognosis of Psychoneuroses.—Römer first mentions essential or acquired neurasthenia, a condition free from any degenerative substratum which is also known as the constitutional form. Kräpelin and Cramer have dwelt particularly on the former. The two forms differ notably, but separation is by no means always easy. The acquired form is seldom seen in sanatoria, for doubtless a healthy subject is inured to bodily and mental strain; so that an unusual causal nexus is required to produce it, or perhaps a persistency in a given causal factor. Thus incessant work without sleep or recreation should surely in time produce a persistent state of exhaustion, which demands an adequate period of rest for recovery. In a case cited neurasthenia was produced in a robust man by protracted labor complicated with illness. The symptoms were headache, vertigo, insomnia, anorexia (with loss of weight), fatigue, inability to work, depression. He readily recovered his full working capacity after a complete rest. The author finds notes of but twelve such cases in his records. Recovery occurred in from one to four months. Associated with degenerative neurasthenia, the three forming a group, are cyclothymia and hysteria. Here the exhaustive state is habitual. Rapid exhaustibility is the rule here, which forms a great handicap in the struggle for existence. Every task is an effort. Peculiarities of temper are early in evidence—depression, anxiety, irritability. In some cases the affection is restricted largely to malaise, and neither hysteria, neurasthenia, nor cyclothymia is in evidence. Cyclothymia or periodical depression often seems to depend on the recurrence of a bodily ailment, as a dyspepsia. All these types of disease shade into one another, so that we see hybrids of hysteria and neurasthenia, neurasthenia and cyclothymia, etc. In any of these affections psychic symptoms may be prominent. Degenerative neurasthenia is very common, and the author has notes of 134 cases, as against 101 of hysteria and 65 of cyclothymia. Twenty-eight cases are put down as simple error of disposition. The recoveries are given as follows: Degenerative neurasthenia, 72.5; cyclothymia, 77.5; hysteria, 71.5—these percentages agreeing fairly well. The proportion of recoveries in disorder of disposition was considerably less—not much over one-half. Many of these patients were under treatment for many years. The relatively large proportion of recoveries is ascribed largely to psychotherapy.

Conservative Treatment of Furuncle.—Keppler of Professor Bier's clinic devotes much space to this subject. Only the worst class of cases is considered—furuncles of the upper lip such as threaten thrombophlebitis. In some of the cases the latter termination seemed to be impending. It is known that treatment by incisions often seems to precipitate a fatal ending. The treatment is precisely that also advocated for malignant pustule—both types of lesion resembling each other so closely as to merit a comon designation "anthrax," and in their nature these are not so entirely unrelated as has been assumed. As the long article is devoted wholly to answering Wrede's criticisms the technique is not given in detail, but we assume it to be that commonly taught as conservative management in general.

Local and General Changes Associated with Death from Burning.—Raysky notes that in this condition the toxins produced by the burned tissues are the cause of death, acting directly on the nerve centers. The changes in the heart, liver, and kidneys are accompanying phenomena, which have no proportionate relationship to the severity of the burn or to its fatal outcome.—*Virchow's Archives.*

Insurance Medicine.

Some Affections of the Liver and Bile Ducts in Relation to Life Insurance.—W. J. Fenton, in this paper, deals chiefly with hepatic cirrhosis and cholelithiasis. The relation of hepatic cirrhosis to life insurance must be mainly concerned with that stage of the disease which precedes the formation of ascites, when the diagnosis is uncertain and the amount of damage which has taken place within the liver is difficult to estimate. Of course, ascites alone is sufficient cause for rejection. Hereditary factors are unimportant. The part played by alcohol in the production of cirrhosis is somewhat uncertain. It is a powerful factor but not by any means an essential one. The constant toper is more likely to contract cirrhosis than the periodical drinker. An important feature is the frequent latency of cirrhosis. Dyspepsia is the earliest manifestation, but the most striking symptom is hematemesis, and years may elapse between this occurrence and the development of ascites. Melena may be also noticed at the same time as hematemesis, but it may occur independently and be due to causes acting in the intestine similar to those which produce hemorrhage of the stomach. A positive opinion cannot be given with regard to the significance of the occurrence of hematemesis or of the size of the liver as determined by palpation. When the applicant is young, the liver only slightly enlarged, and definite symptoms have not arisen, or perhaps slight coffee-ground hematemesis has occurred some years before, and there is assurance of improved habits, a short endowment with an addition might be considered, but when there is clear and definite evidence of cirrhotic degeneration, or when copious hematemesis has taken place, insurance upon any practicable terms is not possible.

In the case of cholelithiasis, in dealing with an applicant for insurance in whose past history there occurs an attack of biliary colic, there is certain information which it is essential to have, of which the more important aspects may be briefly summarized as follows: (1) How many attacks have occurred and how long were the intervals between them? (2) Was the attack followed by jaundice? If not, it should be regarded as of a more uncertain nature from the point of view under consideration than where jaundice has occurred, from the inference that the stone may still be in the gall-bladder or cystic duct. (3) Does careful palpation reveal any enlargement of liver or gall-bladder? (4) Is there reasonable ground to suppose that the applicant is able and willing to adopt a mode of life in accordance with the necessities of the case? Having obtained information upon these points the only conditions upon which an application for insurance could be considered would be a single attack of colic with or without jaundice, uncomplicated, there having been no recurrence after two to three years, in an applicant who otherwise would be acceptable at ordinary rates, with the reservation that, when jaundice has not occurred at a normal interval after the painful seizure, very careful examination of the hepatic region would be needful.—*Transactions of the Life Assurance Medical Officers' Association*, London, 1910.

Syphilis Versus Accident and Life Insurance.—S. G. Burnett notes the frequency of accident and death claims actually caused by syphilis, but attributed to other conditions. Syphilis is a widespread disease. It attacks the nervous system in one case in every ten of infection. The irreparable damage thus done to the nervous system impairs function and subjects the patient to various accidents in getting about and in performing ordinary duties, so that there is a rich and masked cause of assumed accidents and fatal organic tissue changes. A patient may intentionally or unintentionally describe a supposed accident so plausibly as to cause the unsuspecting physician to attribute a continued organic condition to the inferred accident and to affirm his claim for insurance as being just, or, be unable to disprove it. Add to true syphilis of the nervous system the parasyphilitic degenerations of the cord, and the field for acidental assumptions is great. And last, but not least, the syphilitic and parasyphilitic diseases of the brain which cause paralysis, insanity, and death, are a heavy toll in death policies, for the real cause of death is seldom if ever written in a certificate. Tuberculosis is of minor importance in losses compared with syphilis. The author illustrates his statements by citing a number of cases occurring in his practice. One of these was an individual who developed tabetic osteoarthropathy (Charcot's disease) of the right knee, following a slight blow received from a swinging door. Amputation of the leg above the knee was performed. This man carried large accident insurance and demanded it. Thirteen years after he had contracted syphilis a slight, apparently causeless enlargement of the right knee occurred. He then had the cardinal symptoms of Charcot's disease. In the meantime he had negotiated his policy and was accepted as a good risk because of the faulty examination or the faulty requirements for accuracy in examination. The policy was canceled. A second case reported is that of an individual who, ten years after syphilitic infection, developed tabes, and in the course of his work sustained a fracture of the femur. The deep reflexes and pain sense were absent, while tactile and muscle senses were defective. The friability of the diseased bone made the shaft unable to withstand the normal contractile power of the muscles in supporting the body weight. The patient made a good recovery from the fracture, but no payment was made on the policy because the fracture resulted from a disease voluntarily contracted prior to the life of the policy, and was present and not made known at the time of applying for and receiving the policy. A third case reported is that of an individual with syphilis of the spinal cord, who, as the result of injuries received from falling down stairs, was receiving for some time a payment of $50 per week on his accident policy. Upon discovery of the syphilitic condition payment was stopped and the policy canceled. Another case reported is that of an individual with syphilitic paraplegia, who sustained complete disability following an accident, and whose policy was paid in full. An instance is reported of a verdict of $35,000 being given the victim of an accident, and $10,000 accident and $10,000 old line insurance, for the victim died later from the progression of cord syphilis. The author details reports of cases of nervous diseases treated in his sanatorium during a period of six years, a total of 1,741 cases. Of these, 11.3 per cent. were caused by syphilis. The total amount of death claims paid was $104,000, and the total accident claims paid to avoid litigation was $4,625. The total average amount of each claim was $5,200. All the deaths were due to brain syphilis or paresis. There were sent to the asylum to die 26 cases of paresis, of which 21 carried life policies to the extent of a total of $100,000. There were 9 accident claims canceled or allowed to lapse. Of 89 cases of brain syphilis discharged, most of the patients seemed well, but carelessness of the after-care allowed most of them to lapse, the progressive nature of the disease making life uncertain and usually short. Of these 89 cases 60 carried policies to the total of $26,000. There were 24 accident policies canceled or allowed to lapse. A total insurance of $45,000 was carried by 10 of 23 cases of cerebrospinal syphilis; 11 cases carried accident policies, and weekly payments had been made to four of these. Six out of 12 cases of spinal syphilis carried a total life insurance of $31,000. Of 39 cases of tabes 15 carried a total life insurance of $69,000, 10 had accident policies, and 5 had drawn weekly payments for a time. With few exceptions the policies had

been negotiated after contracting the infection — in many of the cases being taken as a means of protecting the wives. It is noted that syphilitic and parasyphilitic nervous diseases occur at the ages of 20 to 40 years, usually at the ages of 25 to 35 years, but some few cases are seen prior to 20 and after 40 years of age. The author's statistics show two prominent age epochs of primary infection: first, 17 to 25 years of age; second, a later period, among married men, when the wives are in the climacteric age and thereafter. For 25 years the author has closely observed the financial status of "syphilis versus accident and life insurance." To present the facts obtained he has carefully itemized the essential features of each case as seen in his sanatorium work during the past six years. In that time $104,000 was paid in death claims and $4,625 in accident claims to avoid litigation; and he has rejuvenated and dropped temporarily 151 men back into the business sea there to shortly offer in solace, for tears long run dry, a policy compensation of $395,000, when they died — and 26 terminal paretics passed the asylum gates to await the collection toll of an even $100,000. Approximately the figures represent a half million dollar penalty for those who avoid the white plague in playing the game of life's expectancy, but who blindly incorporate the glimmer of the red. The question arises what would the penalty be if every physician in the United States could give accurate statistics for six years' work?—*The Medical Fortnightly*, June 10, 1911.

Traumatic Neurasthenia—An Outline.—G. Grahamsley Howitt defines neurasthenia as a functional disturbance of the nervous system characterized by weakness and irritability, lying between hysteria on the one hand and insanity on the other, occasionally overlapped by one or the other, far more frequently the former. Traumatic neurasthenia is that form of the disease which is associated with physical injury and shock, or with emotion and fright, most commonly with a combination of both. Symptoms are almost entirely subjective and principally referred to the nervous system. As the symptoms of neurasthenia are principally subjective, they lend themselves to malingering, although Howitt thinks malingering pure and simple is rare. What is common is for a patient to persist in the belief that he still has the symptoms with which he has become familiar, but which have really disappeared. The prognosis of traumatic neurasthenia is almost invariably good with regard to treatment. The abuse of the bromides is warned against. Too prolonged rest is not beneficial. As soon as possible some occupation, mental at any rate, should be found. Such patients are best treated away from home and sympathizing friends.—*Transactions of the Life Assurance Medical Officers' Association*, London, 1910.

Decreasing Death Rate Due to Certain "Causes of Death" Only.—Charles G. Reiter says that the object of this paper is to show that the decrease in the death rate is almost wholly confined to certain "causes of death," while an actual increase in the death rate has resulted from the diseases that attack principally older lives. The author has taken for the purpose of illustration the statistics of death, with the exception of those under one year of age, in New York City as shown by the annual report of the Board of Health for 1890, 1900, and 1905, and those among insured risks for the years 1891, 1901, and 1906. The New York City population table shows a total improvement in the mortality of 1905 over 1890 of 4,364 deaths per 1,000,000 living, and an improvement over 1900 of 1,540 per 1,000,000 living. An analysis of these figures, however, reveals the fact that this improvement is not contributed to uniformly by all diseases, but is accounted for by the improvement in the mortality caused principally by five groups, viz., miasmatic, malarial, diarrheal, tuberculous, and respiratory. In the diathetic, nervous, and circulatory diseases there were 4,016 deaths during 1905 for each 1,000,000 at risk as against 3,301 during 1890, an increase of 22 per cent. For the fifteen-year period from 1891 to 1906 the results upon insured industrial lives differ somewhat, inasmuch as those of only one group, developmental diseases, show an increase in the death rate; but even among these lives the decrease in the zymotic, tuberculous, and respiratory groups is most marked and shows 70 per cent. of the total decrease. For the five-year period from 1901 to 1906 the decrease in the death rate among insured industrial lives corresponds more closely to the death rate of New York City and is principally confined to miasmatic, diarrheal, and respiratory diseases. The tuberculous and diathetic groups show about the same death rate as in 1901. From the foregoing it would seem that we should not expect so rapid a decrease in the mortality rate in persons over one year of age in the future as in the past fifteen years, and the greatest decrease will probably be in the zymotic, constitutional, and respiratory groups of diseases, with the greatest increases among those affecting the nervous, digestive, circulatory, and urinary systems.—*Proceedings of the Twentieth Annual Meeting of the Association of Life Insurance Directors.*

Statistics of Suicide in the United States.—Frederick L. Hoffman states that the combined suicide rate of 100 American cities, which was 21.8 per 100,000 population in 1908 and 21 in 1909, fell to 19.7 in 1910. The rate for New York was 18.9. San Francisco has the highest suicide rate of any city in this country, the figures reaching a yearly average of 52 per 100,000 inhabitants for the period from 1900 to 1909, although in 1909 the rate fell to 42. Of six American cities in which suicide has been most frequent in the past ten years, five are Californian cities; these, in the order of their suicide rate, are San Francisco, San Diego, Sacramento, Los Angeles, and Oakland. Hoboken, with a suicide rate of 35, is third highest in the list of 100 cities. There was a general falling off in the number of suicides during 1910. Mr. Hoffman states that suicide is often caused by temporary mental irresponsibility, but it is also often the result of a suicide intent which has extended over a period of years. The increasing complexity of modern life favors mental and moral discontent, which is often assumed to be identical with mental irresponsibility. The more the underlying causes of suicides are considered the stronger becomes the conviction that many suicides are the result, not of a want of mental balance, but rather a deliberate conviction that continued existence would not be worth while. Perhaps no occupation emphasizes this conclusion more precisely than the frequency of suicide among bankers and brokers, where a long career of dissipation and fraud often makes suicide the only desirable alternative. Whatever may be said of suicide in the past, it is certainly relatively common among sane men and women to-day. The present decrease of suicides in American cities is only temporary. This is shown by the fact that, whereas in 1891 the rate was only 13½, during each five years since then the rate seems to have gone down and then to have gone up, but always ends by reaching a higher point at the end of each period. The smaller the city the lower the suicide rate tends to be. The suicide rate of a well-developed, prosperous country ought not to be more than 25 suicides per 100,000 population, according to German statistics. Suicides by male Germans seem to have reached their rate limit, having remained at 35 per 100,000 for a long time. But suicide among German women is constantly increasing. Only about 24 American men commit suicide in every 100,000, while only about 7.6 American women in every 100,000 commit suicide. A decided fall in the rate of business failures in 1892 corresponded to a similar fall in the suicide rate, followed by a rapid rise in both rates during the panic year of 1903. But the economic condition of the nation is of course only one of many factors which determine the degree of suicidal frequency.—*The Spectator.*

Book Reviews.

Prevention of Infectious Diseases. By Alvah H. Doty, M.D., Health Officer of the Port of New York. Price, $2.50 net. New York and London: D. Appleton and Company, 1911.

This little work is both timely and valuable. The views expressed are the result of the large personal experience and investigations of the author, who has shown how to protect the health of a large seaport and so, indirectly, of the whole country, with the least annoyance and expense to the public and to commerce. With regard to the transmission of infectious diseases, the author presents the latest knowledge and shows that the theory of "fomites transmission" is not now to be accepted as fully as it formerly was. The infectious diseases discussed in the volume are: Smallpox, yellow fever, typhus fever, cholera, and plague. There are also chapters on: Classification of infectious diseases, Marine sanitation, Disinfection, Disinfectants, the Thermometer, and the Mosquito. The book will prove entertaining and instructive to all who are interested in knowing how the health of our country is maintained and protected; and a wide circulation of the volume will do much to facilitate the duties of our health officers.

The Practical Medicine Series, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School; and Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Volume 1. General Medicine, edited by Frank Billings, M.S., M.D., head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. Salisbury, A.M., M.D., Professor of Medicine, Chicago Clinical School. Series, 1911. Price, $1.50. Chicago: The Year Book Publishers.

This volume is a synopsis of the literature of the past year dealing with some of the infectious diseases, diseases of the lungs and pleuræ, heart, blood-vessels, blood and blood-making organs, ductless glands, metabolic and kidney diseases. The use of a book of this nature affords the busy physician a very ready means of keeping himself informed in regard to the advances in medicine.

Alcoholic Fermentation. By Arthur Harden, Ph.D., D.Sc., F.R.S.; Head of the Biochemical Department, Lister Institute, Chelsea. Price $1.25. London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1911.

The list of titles of the series of "Monographs on Biochemistry," edited by R. H. A. Plimmer and F. G. Hopkins, has now reached very considerable proportions, and the various volumes are being recognized as exceedingly valuable summaries of knowledge in their separate provinces. The present is both in its subject and in its execution fully equal in importance to the others of the series, and furnishes a complete résumé of what is known on the subject of alcoholic fermentation. The opening chapter is a most interesting historical introduction in which the work of the earlier investigators is reviewed, and in the remainder of the book the preparation of zymase and the technique of experimentation with this substance and the coenzyme of yeast juice are described at length. The interesting relationship of the phosphates to fermentation is discussed, as well as the action of inhibiting and accelerating agents, and the volume closes with a chapter on the general mechanism of fermentation as at present conceived. As in the other volumes of the series, an extensive bibliography is appended.

Biblisch-talmudische Medizin. Beiträge zur geschichte der Heilkunde und der Kultur überhaupt. Von Dr. Julius Preuss, Arzt in Berlin. Price M. 20. Berlin: S. Karger, 1911.

Although it is probably true that the author is correct in saying that the number of letters in the Bible is exceeded by the number of commentaries that have been written on it, it is probably also true that the medicine of the Old Testament and the Talmud has never before received such extensive and particualrly such philologically detailed discussion as in the present volume. Indeed, most medical readers would undoubtedly have forgiven Dr. Preuss had he been a little less meticulous in his argumentation on Hebrew roots, or at least had separated such discussions from the body of the text, so as to allow more uninterrupted enjoyment of the really interesting historical material presented. It must be regarded, however, as a great benefit to medical history to have had this work so thoroughly done by a competent philologist, and one may easily believe that it represents the labor of twenty years of research carried on in the leisure moments taken from the life of a general practitioner. It would be difficult to conceive of a more exhaustive treatment of the subject, and the book will be found an invaluable mine of information for all those interested in the subject.

A Textbook of Medical Diagnosis. By James M. Anders, M.D., Ph.D., L.D.; Professor of the Theory and Practice of Medicine and of Clinical Medicine, Medico-Chirurgical College of Philadelphia; Officier de L'Instruction Publique, etc., etc., and L. Napoleon Boston, A.M., M.D.; Adjunct Professor of Medicine, Medico-Chirurgical College; Physician to the Philadelphia General Hospital; Pathologist to the Frankford Hospital. With 418 illustrations in the text and 25 plates, 17 of them in colors. Price $6.00. Philadelphia and London: W. B. Saunders Company, 1911.

Thanks to a steady improvement in the methods of laboratory and instrumental investigation, the diagnosis of medical conditions is approaching a period when it may almost be termed an exact science. This increase in accuracy is to be attained, however, only at the expense of the resort to more or less complicated procedures, and requires a mass of detailed information undreamt of a generation ago. It is not astonishing, therefore, to find that this newest and most comprehensive addition to the list of works on diagnosis is a volume of 1,200 closely printed pages, illustrated by nearly 450 figures, most of them original. The association in its authorship of a celebrated clinician and a well-known laboratory worker is most fortunate, and insures a well balanced treatment of problems that can be authoritatively discussed only by those having special knowledge and training in both of these fields. Careful examination of the book shows that the aims of the authors have been most fully realized, and that they have produced a textbook and work of reference that must long occupy a preeminent position in medical literature. The feature that is most likely first to impress the reader is the admirably systematic fashion in which the material is arranged. Every aspect of each condition excepting only the treatment, is presented in a definitely uniform manner, beginning with a brief description of the underlying pathological changes and frequently including descriptions of the clinical course of actual cases. The possible laboratory aids are given under the subheading "Laboratory Diagnosis," and the whole question of diagnosis is reviewed and the salient points emphasized in a paragraph, "Summary of Diagnostic Features." Abundant use is also made of elaborate differential tables in which the points of similarity and difference of clinically similar conditions are arranged in parallel columns. The illustrations are all exceedingly ingenious and instructive, and deserve especial commendation. It goes without saying that all of the modern methods, such as radiography of the gastrointestinal tract, bronchoscopy, esophagoscopy, opsonic and serum tests, etc., receive adequate description and illustration. The chemical procedures mentioned are apparently all such as may be carried out by the man in ordinary practice, and their significance is clearly indicated It would certainly require the closest scrutiny of the book to discover anything deserving criticism, and the reviewer can have nothing but praise for the work and congratulation for authors on the completion of a task of unusual magnitude and utility.

Studies in Cardiac Pathology. By George William Norris, A.B., M.D., Associate in Medicine at the University of Pennsylvania, Visiting Physician to the Episcopal Hospital of Philadelphia, Assistant Visiting Physician to the University and to the Philadelphia General Hospitals, Physician to the Medical Out-Patient Department of the Pennsylvania Hospital, Fellow of the College of Physicians of Philadelphia, etc. With 85 original illustrations. Price $5.00 net. Philadelphia and London: W. B Saunders Company, 1911.

This exquisitely illustrated series of studies in cardiac pathology is a credit to American authorship and American publishers. Even without the accompanying text the plates furnish a very complete and satisfactory atlas of cardiac disease. The lesions of the various valves are first taken in order, then follows pericarditis, then dilatations and hypertrophies, then aneurysms, and finally congenital lesions. Practically all the important cardiac conditions are illustrated. The individual histories are carefully abstracted and are very instructive. The current text is useful and sufficiently full. The bibliography is quite complete and the index excellent. Altogether it is a monograph of great importance to those interested in diseases of the heart.

Transactions of the American Pediatric Society. Twenty-second Session, held at the New Willard Hotel, Washington, D. C., May 3, 4, and 5, 1910. Edited by Linnæus Edford La Fétra, M.D. Volume XXII. Reprinted from Archives of Pediatrics, 1910-1911. New York: E. B. Treat & Co., 1911.

The high plane that has been established by pediatrics in America is illustrated by a glance at the table of contents of this book. The addresses which are reprinted from the *Archives of Pediatrics*, and which are familiar to those who have closely followed recent pediatric literature, include, among others, articles on the stomach contents and motility in breast and bottle-fed infants by Heiman; substitute feeding in premature infants, by Ladd; height, weight, and epiphyseal development, by Rotch; the new reflexes in meningitis, by Morse; the cytodiagnosis of tuberculous meningitis, by Dunn; retained intubation tube by Northrup; chronic rheumatoid arthritis, by Koplik; food reactions in the infant's stomach, by Cowie and Lyon; the nutrition of the feeble infant by Chapin; fat in the diet of infants, by Howland and Cooke; various phases of poliomyelitis, by Holt, Flexner, Snow, and Lange; amyotonia congenita, by Griffith; vaccines, by Hamill, Howland, and Hoobler; cold-air treatment, by Griffith, La Fétra, and others; acute pericarditis, by Bovaird; empyema, by Huber; and various obituaries, by Jacobi.

Formulaire, Consultations Médicales et Chirurgicales. Par MM. G. Lemoine, Professeur de Clinique Medicale; E. Gérard, Professeur de Pharmacie et de Pharmacologie; avec la collaboration de M. E. Doumer, Professeur de Physique Médicale, et J. Vanverts, Professeur Agrégé, Chirurgien des Hôpitaux à la Faculté de Médecine et de Pharmacie de Lille. Cinquième Edition, conforme au nouveau Codex, 1908. Price 7 francs. Paris: Vigot Frères, 1911.

This is a compact thin-paper volume of 1,000 pages, furnishing a complete *vade mecum* for the physician and surgeon. The first part discusses the art of prescribing and of administering drugs in various ways; and presents a succinct description of the materia medica with the inclusion of many useful prescriptions. The second part consists of an alphabetical index of diseases, with the outline of their treatment. The third section deals with surgical diseases, while the following section takes up the subject of skin and venereal diseases. There are also sections on dietetics, mineral waters, and sanatoria. This volume may be recommended as a useful mine of information.

Les Interventions Médicales d'Urgence. Par G. Lemoine, Professeur de Clinique Médicale à la Faculté de Médecine et de Pharmacie de Lille. Médecin de l'Hôpital Saint-Sauveur. Price 6 francs. Paris: Vigot Frères, 1911.

The scope of this volume of 369 pages is the discussion of those minor surgical procedures that are necessary in the work of the modern internist. These procedures include the technique of serotherapy and hypodermic injections, the diagnostic exploration of serous cavities, the application of setons, leeches, and the cautery, the performance of venesection, enteroclysis, etc. The greater part of the volume is devoted to a description of the indications and contraindications of the various surgical interventions of internal medicine. Thus, under phlebotomy are given its definition, history, indications, contraindications, physiological action, site of election, and operative technique. An important section of the book is that which deals with the various forms of lavage and hydrotherapy. The section on hypodermic medication is particularly complete. This volume presents a most useful contribution to medical literature.

The Anatomic Histological Processes of Bright's Disease and Their Relation to the Functional Changes. Lectures delivered in the Russell Sage Institute of Pathology, City Hospital, New York, during the winter of 1909, by Horst Oertel, Director of the Russell Sage Institute of Pathology. Illustrated. Price $5.00 net. Philadelphia and London: W. B. Saunders Company, 1910.

There has been a feeling abroad of late that the age of the old morphologist was passing rapidly, if it had not already gone, and that our modern era of pathology was that of the dog rather than of the human being. It is a pleasure, therefore, to welcome a purely anatomical study of Bright's disease, especially as it is the product of the Russell Sage Institute of Pathology of the City Hospital of New York, an institution whose accomplishments in the line of general pathology are well known. The modern physician is apt to listen with envy to the skilled Latin of his German colleagues, and, while our author is inclined to be hard on us by somewhat lengthy quotations from the old authors to which he does not always furnish a translation, the cynic will smile to see on page 21 that cynanche is spelt with an "s," thus following an old Greek form which obscures the canine ancestry of the word. The statement (page 5) that albuminous urine contains less urea than normal urine may be true, but often is not. This no doubt will be corrected in an ensuing edition, and such slight slips do not injure the splendid scientific attitude which dominates all of the discussion on the various phases of nephritis. The first lecture is a discussion on the history and classification of Bright's disease; the second is on the structure and function of a normal kidney; the third on the degenerative and exudative features of nephritis. The older ideas of Virchow, which have been replaced to a certain extent by those of Weigert, are very fully presented, including the later views of Ribbert. The writer has no uncertain ideas of his own concerning the various cellular changes which take place in the glomeruli and tubules in this phase of the disease. The subject is continued in the fourth lecture, while the fifth is devoted to productive nephritis, changes in other viscera, and edema. It is difficult to praise sufficiently the clear and satisfactory way in which the complex lesions are presented. The cuts form a prominent portion of the book; those in color are admirable. The photomicrographs, however, leave much to be desired; many of them show optical defects evidently due to imperfect illumination and use of lenses of too low an aperture. The centering of the illuminator is also often imperfect.

Chemistry of Food and Nutrition. By Henry C. Sherman, Ph.D., Professor in Columbia University. Price, $1.50 net. New York: The Macmillan Company, 1911.

It is natural that a chemist should be interested largely in the purely chemical aspect of food, and that a physician should be well equipped to handle the question of nutrition, but the two best books which we have on these subjects are those by this author and by Graham Lusk, neither of them physicians. This volume is somewhat simpler and less technical in its treatment of the subject than is Lusk's, being evidently intended chiefly for undergraduate students, and yet it contains, expressed in simple language, all of the useful knowledge on the subject of nutrition which may now be considered as beyond the need of further proof. Merely contentious matter has wisely been omitted. A sufficient bibliography is appended to each chapter. The printing, binding, and make-up of the book are admirable. Every physician, including him who talks learnedly of calories without any knowledge as to what a calorie is, will be benefited by a perusal of this excellent volume.

Yearbook of the United States Department of Agriculture. Washington: Government Printing Office, 1911.

The 1911 "Yearbook" contains the Report of the Secretary and a large variety of interesting essays on various cognate subjects. Among them may be mentioned particularly papers upon Second-Growth Sprout Forests; Nitrogen-Gathering Plants: The Game Market of To-day; Saving Forest Waste; Good Roads Movement; Insect Enemies of Tobacco; Cheese in Diet; Cooperation in Handling and Marketing Fruit; Camphor Cultivation in the United States. The articles seem to be quite up to the usual standard.

Cholera and Its Treatment. By Leonard Rogers, M.D., F.R.C.P., F.R.C.S., B.S., I.M.S., Physician Cholera Wards, Medical College Hospital, Calcutta; Professor of Pathology, Medical College, Calcutta; Fellow of the Calcutta University; Fellow of the Asiatic Society of Bengal; Corresponding Member of the Philippines Medical Society, the American Society of Tropical Medicine, the American Climatological Association, and the Société de Pathologie Exotique; Mary Kingsley Medallist for Research in Tropical Medicine. London: Henry Frowde, Oxford University Press, and Hodder & Stoughton, 1911.

The author goes very carefully into the history of the cholera epidemics and the lessons that were derived from them. In the opening paragraph on treatment Dr. Rogers says: "The mortality figures already given prove conclusively that no material advance in the treatment of the disease resulted from the greatly increased knowledge of the causation and pathology of cholera during the latter half of the nineteenth century." Therefore, in the chapter on treatment the author first considers the older Anglo-Indian writers and later discusses in detail the principles of modern therapy and the treatment of special indications. The book is extremely interesting from a historical and scientific viewpoint, but is of little practical value to the American physician, as cholera is so seldom met in this country.

The Fats. By J. B. Leathes, M.A., M.B., F.R.C.S., Professor of Pathological Chemistry in the University of Toronto. Monographs on Biochemistry edited by R. H. Aders Plimmer, D.Sc., and F. G. Hopkins, M.A., M.B., D.Sc., F.R.S. Price $1.25 net. London: Longmans, Green & Co, 1910.

The chemistry of the fats has been always somewhat unattractive, possibly because there are no convenient and simple methods for the isolation of the fats and fatty acids from their mixtures, nor for their quantitative determination, such as exist, for example, in the phenylhydrazin compounds of the sugars and the simple quantitative determinations of the latter, depending upon their reducing properties, as aldehydes or ketones. Nevertheless, the important relationships of the fats to metabolism, to the production of fatty acids in diabetic acidosis, to the myelin bodies, and so-called fatty degeneration of the tissues, in which the lecithin compounds play an important part, all these and many other factors have kept chemists hard at work on the character, nature, and estimation of fat. As an illustration it may be pointed out that one of the most frequently employed laboratory methods is the extraction of fat from feces, milk, etc. Despite, however, all the refinements, our present methods of quantitative fat analysis are insufficient, and even our knowledge of the composition of some of the more complex phosphorized fats is still very imperfect. Much that we do know concerning the fats has been collected in this monograph, which is one of the best of the series. The first portion is given up to the general composition, then follows extraction and estimation and the properties of the fats, a field in which the author himself has contributed a good deal by his own researches. An excellent and much too short section is devoted to the rôle of fats in body phenomena. A very satisfactory bibliography completes an extremely useful and compact presentation of a subject of the utmost importance to the biological chemist.

The Nature of Enzyme Action. By W. M. Bayliss, D.Sc., F.R.S., Assistant Professor of Physiology, University College, London. Second Edition. Monographs on Biochemistry edited by R. H. Aders Plimmer, D Sc., and F. G. Hopkins, M.A., M.B., D.Sc., F.R.S. Price $1 20 net. London: Longmans, Green & Co., 1911.

Our growing appreciation of the importance of enzymes in many of the metabolic processes of the body renders especially welcome this admirable monograph on the nature of enzyme action. While the text is not burdened with contradictory details and debatable matter it is sufficiently full to give a thorough survey of the field. A bibliography of some 270 titles affords the student an opportunity of continuing his reading on any one point on which he desires further information.

Der gegenwärtige Stand der Pathologie und Therapie der Gallensteinkrankheit. Von Dr. Ludwig Arnsperger, Privatdozent für Chirurgie an der Universität Heidelberg, I. Assistenzarzt der chirurgischen Klinik der Universität. Price, marks, 2.00. Halle a. S.: Carl Marhold, 1911.

This pamphlet of eighty pages forms part III of the third volume of a collection of short treatises on diseases of digestion and metabolism. It is devoted to the pathology and therapeutics of gallstones, and being written by a surgeon it naturally lays chief stress, and quite properly, upon surgical methods of treatment, though the details of operative technique are not given. The first portion, on the pathology, contains many clinical facts and yet covers on the whole all that we know of the origin of gallstones. Sufficient stress, however, is not laid on the fact that the gall-bladder is probably the depôt for typhoid bacilli in carriers, and the appearance of gallstones long after the patient has suffered from typhoid fever is also not sufficiently emphasized. There is a good clinical description of the attacks of colic and of the collateral symptoms, including those due to alterations in other organs than the gall-bladder. The medical treatment of gallstones by water cures, etc., is mentioned, but without much enthusiasm. The pamphlet forms a useful review of the subject.

Hypophysis, Akromegalie und Fettsucht. Von Prof. Dr. Bernh. Fischer, Direktor des Dr. Senckenbergischen Pathologisch-Anatomischen Instituts in Frankfurt a. M. Mit 2 Tafeln und 6 Abbildungen im Text. Price, marks, 6.60. Wiesbaden; J. F. Bergmann, 1910.

A great deal of interest is now centered about the anatomy and physiology of the hypophysis, since it has been found possible in a certain number of cases to relieve pressure symptoms due to new growths of this organ, and in some cases to extirpate the tumors. The matter, however, is not quite in satisfactory condition, especially as the mortality of such operations is still extremely high, though the course of the disease renders the sufferers willing to submit to any operation which offers hope of relief. In this very timely monograph the occurrence and nature of the tumors which are noted in connection with the syndrome of acromegaly are fully discussed, and the various theories as to the origin of the disease are detailed. The function of the different lobes and the result of the total extirpation of the organ also are considered at length. The relationship between imperfect development of the hypophysis or injury or pressure on the posterior lobe and lipomatosis is well given, though there is still much experimental work to be carried out to decide some of the obscure points, as, for example, why some forms of malignant tumors of the hypophysis do not cause acromegaly, while adenomatous growths do. The author considers that cases of acromegaly described as occurring without tumor of the hypophysis are doubtful.

Consultations et Thérapeutique Dentaires. Par Dr. J. Estfoule, de la Faculte de Médecine de Paris, et L. Dauzier, Chirurgien Dentiste de la Faculté de Médecine de Paris, Professeur à l'école dentaire de France. Price 4 francs. Paris: Vigot Frères, 1911.

This handbook of 255 pages presents in alphabetical order the treatment of the various dental disorders, including those conditions in and about the mouth that are associated with diseases of the teeth. The subjects of local anesthesia and of asepsis and antisepsis are covered in considerable detail. A large number of formulæ are given, including a great variety of dentifrices, pastes to be employed in the treatment of dental caries, etc. The dental practitioner will find this book an exceedingly useful one.

Health Hints and Health Talks. By E. R. Pritchard, Secretary of the Chicago Department of Health. Price 50 cents. Chicago: The Reilly & Britton Co., 1911.

The book is made up of a number of pithy utterances on the preservation of health. Some of the topics discussed are air and breathing, biliousness, cleanliness, consumption, contagion, outdoors, school children, water, breathing, hot weather hints, infection, overcrowding, ventilation, what to eat, eyesight, and care of infants. As a book for the masses this volume presents in a nutshell the main principles of up-to-date hygiene.

Die Blutdrucksteigerung; vom ätiologischen und therapeutischen Standpunkt. Als Preisaufgabe der Hufelandischen Gesellschaft zu Berlin mit dem Alvarengapreis gekrönt. Von Dr. med. Karl Hasebroek, Leit. Arzt des Hamburger medico-mechan zanderinstituts. Mit 3 abbildungen im text. Wiesbaden: J. F. Bergmann; New York: G. F. Stechert & Co., 1910.

In this essay, which was awarded the Alvarenga prize for 1910, the author discusses the physiological and clinical aspects of blood-pressure from the viewpoint of its teleological nature, or its functional adaptations to the needs of the economy. The technique of blood-pressure determination is not discussed. The author first takes up the subject of the etiological aspect of increased blood-pressure under the following headings: increased blood-pressure and experimental physiology; the peripheral resistance as related to the independent work of the blood-vessels; increased blood-pressure under the influence of circulatory changes, increased blood-pressure and cutaneous activity; also chapters on increased blood-pressure as relates to contracted kidney, affections of the hemopoietic organs, the functions of the central nervous system, the pulmonary activity, and arteriosclerosis. In the second section the author discusses the general and special therapeutic relations of increased blood-pressure.

Plaster of Paris, and How to Use It. By Martin W. Ware, M.D., New York, Adjunct Attending Surgeon, Mount Sinai Hospital; Surgeon to the Good Samaritan Dispensary; Instructor of Surgery, the New York Post-Graduate Medical School. Second Edition, Revised and Enlarged. Illustrated with 90 original drawings. Price $1.25. New York: Surgery Publishing Company, 1911.

The proper application of a plaster-of-Paris bandage is an art acquired only by the few who, like Dr. Ware, have had the opportunity of using it in thousands of cases. After describing the proper manufacture and preparation of the plaster bandage, the author considers its application to the various fractures and its use in orthopedic surgery. One chapter is given to the subject of molded splints. By means of the excellent illustrations one gets a very clear conception of the proper application of the plaster-of-Paris bandage in the treatment of the fractures and deformities of the body. This volume should certainly prove of value as a reference book.

SECTION OF SURGERY.

First Day—Wednesday, July 26.

Treatment of General Septic Peritonitis.—Prof. RUTHERFORD MORISON of Newcastle-on-Tyne referred to the extent of peritoneal surface as almost equal to that of the skin. Death from extensive scalds was probably due to a cause similar to that causing death in diffuse peritonitis. General septic peritonitis was due to a gross lesion resulting in the wide invasion of pyogenic organisms, of which streptococci were the most virulent. Peritonitis might end by (1) resolution, (2) adhesions (fibrosis), (3) local abscess, or (4) diffuse destruction (gangrene). Beyond arresting the supply of germs from the primary focus, operation could deal only with the effects of inflammation. The condition of the circulation was the chief guide as to both the treatment and the prognosis; and it was more important to know how much peritoneum was red and sodden than to know which variety of organism was present. Whatever the germ, the prognosis was good if the pulse was of good volume and not over 100, and bad if there were cyanosis, cold extremities, and a pulse over 120. A sunken appearance and symptoms of shock were said to be due to toxemia—but what was toxemia? He preferred to ascribe those symptoms to disturbance of the balance between the somatic and splanchnic circulations. Peritonitis following germ infection was a protective reaction to be aided, if possible, though it was readily upset. The peritoneum had exceptional immunity to septic infection, and rougher surgery might be perpetrated with impunity inside the peritoneum than would be tolerated by any other portion of the organism. Other defensive aids were free secretion of fluid and plastic formation. The omentum also was often glued in such a position as to prove its value as a life-saving mechanism. Early recognition of the need for operation might be more important than the method of its performance. The speaker's statistics of 427 cases, with 18 deaths, in the Royal Victoria Infirmary, occurring in Newcastle during 1910, were given in the form of a summary. These statistics showed that operation should be done as soon as possible and done in a properly equipped hospital. As to operation, three initial points required attention: (1) The patient must be kept warm; (2) as little anesthetic as possible should be given—by preference chloroform to dull the laryngeal reflex—and then ether; (3) the less disturbance of viscera the better, no rough manipulation being permitted. The incision was made over the causative lesion if this was diagnosed; otherwise the umbilicus should be excised and the abdomen opened in its center; in either case the focus was to be dealt with according to surgical rules. For excluding an irremovable focus gauze tampons were sometimes indispensable, but if possible, gauze should be in contact with omentum and not small intestine. The best method of cleansing the peritoneum was by lavage with decinormal saline solution, at a temperature of 100° F.; but in most cases cleansing was not wanted; the use of dry mops was injurious. With regard to drainage, a good rule was, "When in doubt, drain." A temporary suprapubic glass tube was useful for washing out extravasations during repair of the infecting focus, and removed at the end of the operation. More permanent drainage was sometimes indicated, and the drain should then be pelvic only, and kept empty by Tait's syringe pump.

The "Fowler posture" was most useful, and so was the intravenous infusion of decinormal saline solution to which a small dose of adrenalin was added. A voluminous dressing of wool was applied to produce elastic compression and to retain heat. In the after treatment proctoclysis, stomach lavage, a single dose of morphine, purgation with caution, and digitalis, were all valuable in certain cases. Interference was often of doubtful benefit in cases of general septic peritonitis of more than three days' duration. In acute pneumococcal, gonococcal, post-operative, and puerperal peritonitis, operation was more likely to do more harm than good.

Professor Koch of Groningen held that operative treatment of diffuse peritonitis would always be indicated, so long as specific serum or vaccine treatment was not forthcoming. Moot questions were: (1) When should operation be performed, and (2) what was the best procedure? As to (1) operation could not be too soon, but might be too late if delayed. If appendical cases, which were generally dealt with early, were subtracted from the group, the mortality of the remainder reached a high figure. Thus in Rehn's statistics the death rate of the entire class was 50 per cent., but excluding appendicitis, the rate was 70 per cent. Krogin's figures were respectively 50 and 61 per cent. As to (2) the worst cases should not be narcotised, morphine and local anesthesia being employed; in milder cases he preferred narcosis. Incision over the focal lesion was the best site, the wound going straight through all the layers, the median incision being reserved when the origin of the peritonitis was not known. It was essential to deal effectively with the cause, *e.g.*, by removing a morbid appendix or closing a perforation. Evacuation of pools was effected by his special aspirator, and washing out could be done at the same time by a combined tube which was exhibited. Several incisions might be required to empty peritoneal recesses. Puncture and drainage of the distended gut were recommended, and appendicostomy was spoken of favorably. Drains were left in the peritoneum. In the after treatment persistent vomiting was best treated by continuous drainage of the stomach through a nasal tube, as advised by Westermann. Saline infusion with adrenalin added was of great value; and so was Fowler's position. Kaster's ventral position was always refused by his patients.

Mr. HERBERT PATERSON, London, thought that the Section were greatly indebted to Mr. Rutherford Morison for his masterly and lucid exposition. In discussing this subject it was fitting to remember how much the improvement in our results in recent years was due to the inspiration of our colleagues across the Atlantic. The Fowler position, the importance of rapidity in operating, and the method of continuous proctoclysis, had all been the result of the teaching of American surgeons. The whole operative treatment of diffuse peritonitis was admittedly summed up in Dr. Murphy's pithy remark, which could not be too often repeated, "Get in quick, and get out quicker." He was glad that Mr. Morison emphasized the axiom that operation was indicated in an overwhelming majority of cases. The Ochsner treatment had been misunderstood, and had sometimes been an excuse for delay in cases in which operation would probably have been better. He considered that pneumococcal peritonitis was often very difficult to diagnose, the signs being frequently but slightly marked; the temperature and pulse might be normal, and it was often very difficult to decide whether the patient had peritonitis at all. He agreed with Mr. Morison that operation was contraindicated in pneumococcal peritonitis, but he personally considered that in gonococcal peritonitis operation was indicated. He thought that it was a good working rule that unless one could make a good guess as to the cause of the peritonitis it

was better to postpone operation and treat the patient on the lines laid down by Ochsner. He considered rapidity in operating and avoidance of unnecessary exposure of viscera were the most important operation factors influencing the fate of the patient. Last year Dr. Crile had given the Section an admirable summary of his investigation on shock, and showed how important it was to avoid all possible cause of shock, either mental or physical. For this reason the speaker was an uncompromising opponent of washing out the peritoneal cavity in any shape or form, or under any circumstances. Fortunately, we had long passed the days when patients, after an operation for peritonitis, were placed in baths of antiseptics to flush out the abdominal cavities, or were put back into bed with tubes, Medusa-like, projecting from all parts of the abdomen, through which continuous irrigation was carried out, until the peritoneal cavity could no longer withstand such treatment and revenged itself by the removal of the patient from such misguided energy. He had followed up cases at the time when the fashion for washing out was at its height, and he was convinced that irrigation greatly increased shock, and the shock at operation was echoed in the tardiness of the patient's subsequent recovery. He believed that the peritoneum could deal with foreign matter better than the surgeon, and that as regards washing out, any possible gain was more than counterbalanced by the increased immediate risk. Subdiaphragmatic abscesses were rare if the Fowler position was adopted. Chloroform was absolutely contraindicated in these cases. The greatest advance was continuous proctoclysis, and to the use of ether as the anesthetic the improvement in results was mainly due. (The speaker showed his apparatus for continuous proctoclysis by the Murphy method.) In conclusion he referred to the administration of cathartics after operation. In bad cases his own practice was to commence the administration of small doses of calomel almost as soon as the patient was round from the anesthetic. He believed the evils attributed to peristalsis were exaggerated, and if such evils existed at all they were more than compensated for by the peritoneal drainage and removal of toxic products effected by the use of calomel.

Mr. G. P. Newbolt of Liverpool said that cases of appendicitis giving rise to general septic peritonitis were seen by the surgeons earlier now than even five years ago. Great confusion seemed to exist in the definition of general septic peritonitis, which in his judgment was an infection of the whole peritoneal cavity and not an infection limited to an area around an infected organ. He did not believe that any surgeon could save 96 per cent. of genuine cases of general septic peritonitis. The three factors contributing to success were speedy operation, skill in anesthesia, and efficient drainage with proctoclysis. There was frequently great difficulty in determining when to refuse to operate in these cases, as now and then the most desperate cases recovered after operation. Chloroform, to his mind, was a dangerous drug, and he much preferred ether. He administered a small dose of morphine (1/6 grain) after operation to allay restlessness. The formation of subdiaphragmatic abscess in those recovering from operation for this disease often proved extremely troublesome to deal with, and required careful watching for.

Mr. Grant Andrew of Glasgow said that, given a case of general septic peritonitis, from whatever cause, his practice was first to make a small suprapubic incision, about 1 to 1½ inches in length, opening the general peritoneal cavity. This at once gave valuable information as to whether free fluid was present in the cavity—its nature, its odor, its amount; and as to the condition of the serous lining of the bowel, its vascularity, its degree of distension, and the presence of newly formed adhesions. If in doubt as to the seat of the exciting cause this preliminary incision was of great value because from the nature and character of the free fluid alone a diagnosis could usually be made. Having proved that the fluid was free in the general peritoneal cavity a narrow strip of gauze, with string or tape attached, was passed right down to the pouch of Douglas, and there left meanwhile to act as a drain. The exciting cause was then dealt with. The speaker always, and in every circumstance, exposed the appendix by the gridiron method. This enabled him to close the wound entirely without the risk of hernia. The offending appendix, in this class of case usually gangrenous and possibly perforated with an extruded concretion lying in its immediate neighborhood, was removed in the usual fashion. The stump must be well buried. The bed of the appendix and the surrounding structures were swabbed with iodine, 4 per cent., mopped dry, and the gridiron wound, after similar treatment with iodine, was closed in layers. The upper part of the body was now slightly raised so that all intraabdominal fluid gravitated towards the pouch of Douglas. The gauze placed in the suprapublic wound was then removed and any pus which might have collected in the pouch or in the lower part of the pelvis was mopped out, syphoned out, or sucked out by a rubber tube and syringe. This wound was also closed after the edges had been disinfected with iodine. If the condition of the patient permitted, the Howard position was assumed immediately the patient was returned to bed and proctoclysis was commenced. No risk was run by primary and complete closure of the wound. The speaker believed the presence of packing and the use of a drain, either rubber or glass, was to exert a devitalizing influence on the bowel and to encourage the formation of a fecal fistula. Nothing was gained by leaving the wound open, and furthermore, if it was partially closed and a drainage tube was inserted at the angle of the wound, it was there a hernia would occur. Since September last he had operated upon seventeen cases which came under this category, *i.e.*, free pus in the general peritoneal cavity, without limiting adhesions, and not confined to the pelviperitoneum. The appendix was gangrenous in each case, and the primary cause of the peritonitis. In each case the same technique as above described was practised, both the appendical and the suprapublic wounds were closed. Recovery took place in every case save one, in which death occurred six hours after operation—a hopeless case. In eight out of the remaining sixteen cases primary union of both wounds occurred. In eight cases the wounds became infected in varying degrees, necessitating the removal of the lowermost surface stitch in three of the cases, and of all the surface stitches in another; as the incision was gridiron this did not weaken the cicatrix. In one case a pelvic collection formed which burst into the bowel and was discharged per rectum. In another, pain was complained of in the region of the liver, and with a remittent temperature a subdiaphragmatic collection was feared, but this gradually subsided and finally cleared up. In no case did a fecal fistula result. These records compared favorably with those from any other line of treatment, and proved that subsequent drainage was unnecessary if the exciting cause were removed.

Professor Gilbert Barling said that he was of the opinion that the term general septic peritonitis was often very loosely used, and that many people did not mean quite what they said. This led him to say that he was at variance with Mr. Grant Andrew when he referred to his series of cases where he had successful results following upon immediate closure of the abdominal wound in "general septic peritonitis." He did not think that what Mr. Grant Andrew called septic peritonitis was what he himself always was accustomed to regard as general septic peritonitis. What he (Mr. Barling) meant by that term was that the whole peritoneal cavity was infected right up

to the diaphragm, and he maintained that the vast majority of these cases would not recover, no matter what was done. Another point which he wished to make was as to the nature of the infection. He had great respect for any form of infection, but the one he feared most was streptococcal infection. If he understood Mr. Rutherford Morison aright in saying that it did not matter greatly what the kind of infection was, he felt compelled to disagree with that statement. He narrated a case where he had removed the appendix in a little lad and had regarded the case as one as nearly as possible certain to do well; but that boy died in thirty hours, and when the bacteriological report came it was found to be a streptococcal infection. He was convinced that there was greater danger from infection by that germ than any other. Of course, one did not know the germ till after cultivation; so that the treatment was not affected by the knowledge of the germ, but the prognosis was. As regards the question of incision, he emphatically supported Mr. Rutherford Morison's ideas, and thought no harm came of extensive incisions. It appeared to him that the spread of peritonitis was to a certain extent mechanical. The spread upwards from the appendix region was limited in the middle region of the abdomen by the transverse mesocolon. The mechanical arrangement of the peritoneum had a good deal to do with the spreading or limiting of septic peritonitis. He thought both swabbing and irrigation had their advantages, and one should not exclude the other. If one found a localized collection in the pelvis there seemed no reason why it should not be cleaned out as thoroughly as possible by swabbing. Similarly, if one had to deal with a recent duodenal or gastric perforation one could not possibly swab out all extravasated materials, and it was here that irrigation was most useful. On the question of the treatment of the appendix, he would like to see every case of appendix infection operated upon at once. That was to say that every case should be diagnosed immediately, and should be brought at once into an operating theater; but, unfortunately, delays often took place, the diagnosis was not always accurately made, the patient's friends did not always send for the physician; so it was necessary to take the world as we found it. To make a routine of operation in all these cases directly they were seen, on the second or third day, and to attempt to close the abdominal wound would be in many cases disastrous; while we might guess shrewdly as to the condition of affairs inside the abdominal cavity we could not tell for certain what it was like until we had opened. Sometimes the symptoms were intense in their severity, and the condition found in the appendix region was slight; sometimes the reverse was the case. It was, therefore, necessary that we should adopt no hard and fast line of treatment, but that we should take cases as we found them, and treat each on its own merits.

Dr. J. Crawford Renton of Glasgow said that he was in agreement with all that Mr. Rutherford Morison had said in his paper, and he spoke only to emphasize the importance of urgent cases being operated on without delay. The public was being educated now in many directions of late, particularly was it instructed in the dangers of tuberculosis. He would like to see information regarding urgent abdominal conditions spread more widely if it would tend, as he thought it would, to the more speedy bringing of such cases into the hands of the family doctor and then the surgeon. In speaking of the importance of getting the bowels to act as soon as possible he was accustomed to administer, as soon as the patient had recovered from the anesthetic, small doses of calomel every two or three hours for three to four days, and then to use an ordinary enema. In addition, decinormal saline injections were used. Pituitary gland tabloids he gave before as well as after the operation to counteract shock. The Fowler position should be adopted as soon as possible, and the patient brought into the hospital in that position. Postoperative vomiting was likely to be less if ether (after a few preliminary whiffs of chloroform) was used, and if it did occur it might be treated by stomach lavage which, with the Fowler position, never failed.

Mr. Garnett Wright of Salford said that while in general agreement with the previous speakers, he was at variance with them on the subject of removal of patients to hospitals and nursing homes if their own homes were at all reasonably good. While this did no harm in early cases, it was harmful in those cases which were on the borderland, ready and apt to become grave where the general circulation was beginning to fail. In such circumstances it was better to operate at home, in spite of the fact that the after treatment was more difficult, because these cases might become very much worse by the removal from home. He wished also to emphasize the importance of doing the minimum required to remedy the defect which had caused the peritonitis. In the majority of cases lavage and mopping were unnecessary, and might do harm by prolonging the operation and increasing shock. If these was extravasation of intestinal contents they should be got rid of and the best method was by lavage. In appendix cases no more mopping was required than is necessary to clear the field. After the removal of the appendix free drainage should be provided. In general, free drainage of the septic peritoneal cavity was of greatest value, and in desperate cases might sometimes be employed with success without dealing with the exciting cause. The chief improvement in after treatment had been the use of proctoclysis with continuous saline injection. It was difficult and required special apparatus and good nurses, and was unobtainable in private houses. Where it could be done, intermittent administration supplemented by subcutaneous injections might be employed. As regards the point raised by Mr. Gilbert Barling that all cases should not be operated upon immediately, and that sometimes a case proved worse than it looked, and *vice versa*, the latter statement was a potent argument in favor of operating as soon as possible.

Mr. C. P. Childe of Portsmouth was opposed to the administration of morphine, because it lessened peristalsis, and so conduced to flatulence.

Mr. Bishop of Manchester advocated the giving of pituitary extract to promote peristalsis after operation.

Mr. Bidwell of London also advocated the use of pituitary extract after operation. He was of opinion that it had considerable value in restoring the peristalsis. He was accustomed to give 1 c.c. every four hours for the first two or three days. One advantage of it was that it counteracted the disadvantages of morphine, so that he generally gave at least one dose of morphine (1/6th grain) to give the patient a quiet night. On the question of flushing and wiping out the peritoneal discharges he thought there was no hard and fast rule to be followed. If flushing was done it was absolutely necessary to provide free exit for the fluid. His next point was as to the great value in general septic peritonitis of the use of a rectal drain; an opening was made from within, through the pouch of Douglas, by means of a pair of strong curved forceps into the rectum, and a tube was passed through this opening and then through the anus and stitched to the skin of that region. This permitted closure of the suprapubic wound. The rectal tube he found was frequently removable in two or three days. It had been alleged that if the rectal drain were used it would be impossible to administer saline solution per rectum, but in his experience there was no interference with the administration of salines.

Mr. D. P. D. Wilkie of Edinburgh called attention to the importance of an immediate miscroscopic examination

of the peritoneal exudate at operations on cases of general peritonitis. Such examinaitons in a large number of cases revealed the fact that the particular type of bacterium causing the inflammation was of less importance than the reaction on the part of the patient. Presence of streptococci did not necessarily mean a bad prognosis, provided the cellular reaction was a vigorous one. The important point was the relative number of microorganisms free in the fluid to the number of phagocytic cells. If many of the bacteria were found free in the fluid the prognosis was as a rule a grave one. At post-mortem examinations in cases dying from general peritonitis the jejunum was frequently found greatly distended, whereas the ileum was found collapsed and adherent in the pelvis, and the patient had obviously died partly from a peritoneal, but also partly from an intestinal toxemia. After the operation of opening and draining the abdomen in such cases the inflamed intestines, coming together, adhered, peristalsis was interfered with, and pocketing of pus was very liable to occur. In order to favor peristalsis and free drainage, the speaker had advocated the pouring in of a few ounces of sterile vaseline oil to delay the formation of plastic adhesions. The experimental and clinical results which so far had followed the use of this method had been very encouraging. In the after treatment of desperate cases two methods had been found to be of considerable value: the one was the passage of a continuous oxygen current through the drainage tube in the pelvis. Oxygen was rapidly absorbed by the peritoneum, it excited an active hyperemia which tended to overcome the venous stasis associated with severe cases of peritonitis. In several cases a rapid and marked improvement in the patient's general condition had resulted from the employment of this method. The other method which he had tried in cases which appeared desperate, and after all the ordinary methods of after treatment had been employed, was the injection of blood serum withdrawn from the median basilic vein of another patient in the ward who had just recovered from an infection by the same bacterium. Sixty cubic centimeters of blood were withdrawn from the vein, the serum was allowed to separate, and was then injected into a vein of the patient whose condition appeared hopeless. Of seven patients treated in this way two recovered, and there was little doubt that their recovery was in large measure due to the antitoxin thus administered.

Mr. Bloomer of Stafford narrated the case of a boy whose abdomen he had opened four times within the space of seven months. The primary condition was gangrene of the small bowel, treated by resection and a Murphy button. Three months after recovery the bowel perforated, and was brought to the surface and fixed there one week. The third operation was done to effect lateral anastomosis. A month ago a fourth laparotomy had to be undertaken for the division of bands causing obstruction. The patient was now apparently well, but the button had not been recovered.

Second Day—July 27.

The Technique of Wound Treatment.—Mr. Alexis Thomson of Edinburgh, in opening this discussion, said the subject was a problem in bacteriology. The part played by the tissues, though important, was only secondary, and the first essential in treatment was to prevent the entrance of pathogenic organisms. The principles of Listerism were permanent; the means of carrying them out are always changing. He deprecated the attitude of adopting every new device simply because it was new, no less than the attitude of supposing present results incapable of improvement. The knowledge and skill required for practising Listerian principles were not an end in themselves, but means to an end. He urged that a surgeon should be a trained bacteriologist, and that a laboratory should be attached to every surgical clinic, so that everything in the operating theater could be readily subjected to culture and other tests. The speaker referred to the difficulties encountered in teaching hospitals where students and nurses had to be trained. He then reviewed the methods of sterilization and their reliability as regards instruments, dressings, clothing, and lightness. Finally he discussed the methods of dealing with the skin of the patient and the hands of the surgeon; the phagocytic power of the tissues, and to what extent this could be conserved or increased; and the use of vaccines and serums.

Mr. H. Paterson of London agreed that instruments could not be kept sterile during an operation unless reboiled or kept in antiseptic fluid. He objected to the use of catgut because it was liable to give way too soon; silk or linen was better, and the ability to use these with impunity was a test of the surgeon's technique. To sterilize the hands, his choice was for methylated spirit. Gloves should be dry sterlized, or the hands would not remain sterile. Alluding to an article by R. T. Morris of New York, on "The Iron Hand in the Rubber Glove," he did not find that gloves interfered with his work. In spite of the good results achieved by some non-glove surgeons, *e.g.* Mr. Stiles, he still thought gloves were an aid to asepsis. He regarded the iodine method as the best for the patient's skin. His plan was to rub the skin with acetone on two successive nights before operation, and then paint with the iodine solution (Liq. Iodi fort. ℥i, Sp. vini rect. ℥ii, Aq. destil. ℥i), a final coat being painted on just before the operation

Mr. Newbolt of Liverpool agreed with the necessity of not being satisfied with present results, however good. Gloves were invaluable. As the air was not sterile he advocated the use of antiseptics in conjunction with asepsis. He used equal parts of Tr. Iodi and Liq. Iodi as a paint for the patient's skin—in emergencies without shaving or any other preparation. Clean dissection and the avoidance of bruising often saved after trouble. In bowel, stomach, and mouth cases, careful preparation of the patient was essential. The successful wiring or plating of fractures was a good test of skin preparation and wound treatment.

Mr. Thomas S. Ellis of Gloucester said that the treatment of wounds was dependent not on bacteriology alone. In a cicatrising wound the contraction which was perpendicular to the surface had the effect of fixing the skin at the margin. If this was prevented and the neighboring skin kept movable the contraction which was parallel to the surface of the wound would have the effect of gently drawing true skin from the margin. The true skin might be developed to an extent far greater than was generally supposed. He showed photographs of a child in whom burning had destroyed the whole of the integument from a line just below the margin of the lower lip nearly to the sternum. The skin at the lower edge of the wound was persistently pulled outwards and upwards. By this maneuver so much skin was developed that the usual contraction was obviated and the child could now look upwards with perfect ease. Nothing in the way of skin grafting was done. The same principle was applied by him in dealing with the skin of amputation flaps, and the surgeon should not be satisfied until the skin was freely movable over the stump. This process was assisted by manipulation with a piece of rubber about the size of a sheet of note paper.

Mr. Leedham Green read a paper on "The Value of the Sterilization of the Skin by Iodine." Much had been written on the value of iodine as an agent for sterilizing the skin, but little experimental work had been published to support the claim that it was the most efficient method, and nothing comparing it with the best of the older

methods. In cultural tests made with small portions of ligature silk and glass beads infected with various organisms, tincture of iodine proved to have the greatest bactericidal power when prepared with 70 per cent. alcohol. Comparative tests with tincture of iodine (70 per cent. spirit), plain alcohol (70 per cent.) and an aqueous solution of iodine (same strength as the tincture) showed that while the last named possessed decided germicidal properties it was less potent than the 70 per cent. spirit, which in its turn was inferior to the tincture. Further it was shown that an alcoholic solution of perchloride of mercury (1 in 1000 of 70 per cent. spirit) was superior in bactericidal power to the tincture of iodine (70 per cent. spirit) and still more to the official tincture. Taking the average of a number of tests with different non-spore-bearing organisms: Sublimate spirit (70 per cent. alcohol) sterilized in 2½ minutes; tincture of iodine (70 per cent. alcohol) sterilized in 7 minutes; tincture of iodine P.B. sterilized in 10½ minutes; aqueous solution of sublimate sterilized never under 30 minutes. Comparative practical tests on the skin with plain alcohol, tincture of iodine, and sublimate alcohol showed the marked superiority of the two last named. These proved themselves to be powerful skin disinfectants. A true sterility was never obtained, but both methods always greatly reduced the infectivity of the area. In other respects the results were disappointing. In an unpleasant proportion of cases the skin proved to be still surgically infective. Neither of the two methods could be said in any way to guarantee sterility, for the skin, which had proved to be practically sterile directly after the process of disinfection, gradually became more and more infective as under the imbition of fluid the hardened epithelium became loosened.

Up to the present sublimate alcohol had given the better results. There was a slight superiority even when it was merely painted on the skin like the iodine. When it was freely rubbed on, as in the usual method of alcohol disinfection, the superiority was more marked and at times pronounced.

Mr. C. W. Cathcart of Edinburgh had found the following method simple and successful: Washing and shaving of the skin, then dehydrating with alcohol and painting with Tr. Iodi (B.P.), and covering with a sterile dressing. This was done the night before operation, and the skin was again painted with iodine just before operation. He sometimes used Lord Lister's method of soaking with 1—20 carbolic solution for twenty minutes. He believed that the hyperemia caused by iodine painting was an important factor in the good result. He has been quite satisfied with the iodine-spirit method of preparing and storing catgut. He objected to dry dressings on granulating wounds, and to the packing of sinuses with gauze, preferring moist dressings covered with waterproof in such cases.

Dr. Elder of Montreal drew attention to the experiments in Crile's Clinic. No operation could be aseptic. The air would infect, if nothing else. The whole benefit from iodine or alcohol depended upon the local hyperemia they produced. It was the biological action (as Mr. Cathcart has just pointed out) of these agents upon which we had to depend. The patient must rely upon the phagocytic action of his own blood—determined to that part by the iodine or alcohol—for his protection. Dehydration of the surface meant hyperemia deeper down, and it was this hyperemia which protected, and not the presence or absence of any chemical agent to any particular depth in the skin.

Mr. Cuthbert Wallace of London had not used any so-called antiseptic or chemical for ten years, and relied on soap and water for preparing the patient's skin. Instruments were boiled in water, laid on a dry towel, and rinsed from time to time during operation in sterilized saline solution. He used rubber gloves. In six hundred operations on clear cases, taking the radical cure of hernia as a type, suppuration occurred in less than 4 per cent. These results had been obtained in a teaching school (St. Thomas' Hospital) with all assistants constantly changing.

Lieut.-Col. H. Smith, Indian Medical Service, spoke of operative work in the tropics which had to be done in the open air—often dust laden. Instruments were kept in a 1—40 carbolic solution, and the wound drenched with a 1—2000 sublimate solution. He referred to Sir David Semple's observations showing that tetanus might follow in the case of a wound containing a ligatured anaerobic stump, *e.g.*, the neck of the sac in the radial cure of hernia. The speaker therefore advocated stitching in preference to ligaturing in such cases. He objected to gloves because they lessened the dexterity essential to rapid operating, and rapidity, in its turn, often did away with the necessity of draining a wound. Six months in a workshop would afford better training for a would-be surgeon than post-graduate courses; and a man intending to practice abdominal surgery would do well to spend a few months on a tailor's bench in order to learn how to handle needles and thread.

Remarks were also made by Professor Koch (Groningen), Dr. Douglas Drew (London), Professor Cameron (Toronto), and Sir Thomas Chavasse, president of the Section.

Sarcoma Treated by Radium.—On behalf of Dr. Louis Wickham of Paris, Professor Ryerson of Toronto presented a report on two cases of sarcoma treated by radium with good results. The first case was that of a girl of ten, from whom a sarcoma of a digit of the left foot was removed in February, 1908; recurrence followed, and the front half of the foot was amputated in February, 1910; in August, 1910, a growth appeared in Scarpa's triangle (left), and this had disappeared under Dr. Wickham's treatment by radium at intervals from April 4, 1911, to July 7, 1911. The second case was that of an English boy, aged eleven, from whom a London surgeon removed a large sarcoma of the thigh last April. The growth recurred, and, as amputation at the hip was declined, treatment by radium was undertaken by Dr. Wickham from the 4th to the 9th of July, with the result that the tumor had disappeared. (This patient was shown to the meeting, and examined by many surgeons present.) Dr. Wickham conveyed the opinion that while all operable cases of sarcoma should be treated by operation, radium was an adjunct to surgery, and might be regarded as a prolongation of the surgeon's bistoury, because of its power to penetrate beyond the reach of eye or finger. It was also of value as a means of relieving pain in cases of inoperable malignant growths.

Third Day—Friday, July 29.

Some Functions and Surgical Uses of the Omentum.—D. P. D. Wilkie of Edinburgh read this paper. The omentum was no specialized organ for absorption of fluid from the abdomen. It had a remarkable capacity, however, for picking up any foreign particles of solid matter left in the peritoneal cavity. Removal of the omentum markedly lowered an animal's resistance to peritoneal infection. There was no evidence to show that the omentum was capable of "intelligent movement," or that it was attracted by any infection. It was borne to the zone of irritation by simple mechanical factors. The omentum might with benefit be wrapped round a portion of intestine the vitality of which was doubtful. The use of isolated portions of omentum as grafts to reinforce suture lines could not be recommended, owing to the tendency to extensive adhesions to neighboring viscera. In cases in which a perforation of a hollow viscus could not be closed by the ordinary methods, a plug of omentum

might be relied on to occlude the opening. At the conclusion of his paper Mr. Wilkie gave a lantern demonstration illustrating the uses of the omentum as shown in the effects produced by experiments on animals.

Abdominal Aneurysm and Its Surgical Treatment.—Mr. W. DE C. WHEELER of Dublin reported two cases successfully operated on by himself during the last twelve months. He urged the necessity for extraordinary precautions in asepsis, in the presence of advanced arterial disease and of buried metal. He advised the administration of 606 in recent syphilitic disease, or in the presence of a positive Wassermann reaction. This was a prophylactic measure against the development of a secondary aneurysm or rupture of the aorta. He also advised the injection of horse serum at the time of operation to assist coagulation. He deplored the fact that abdominal aneurysm was not diagnosed until it was almost "pointing," thus defeating the best chance for the cure by operation. Colt's apparatus, he thought, made the operation safe and effective. Mr. Wheeler introduced 150 inches of wire in the form of a cage in his first case, and a wisp of 105 inches in the second. One man was back at work eleven months after operation; the other was only recently treated, but showed a marked improvement.

Appendicitis Without Physical Signs.—Mr. H. J. PATERSON of London read this paper. The appendix might be the seat of gross lesions although the patient had never had a recognizable attack of appendicitis. In acute appendicitis the physical signs might be very slight, in rare cases absent, so that there might be little indication of the serious condition of the patient. Chronic appendicitis might simulate gastric disease with remarkable fidelity. The author gave an account of the symptoms and gastric analyses in these cases. Based on an experience of forty-four cases, he formulated the following important surgical lessons: (1) In operation for supposed gastric or duodenal ulcer failure to discover these lesions suggested examination of the condition of the appendix. (2) In cases of abdominal pain of obscure origin we should bear in mind that the appendix might be the cause, although there might have been no definite clinical attacks of appendicitis. The speaker related cases of acute appendicitis in which physical signs were absent when the patient was seen, and yet operation revealed serious and extensive inflammation of the appendix. Such cases taught that in dealing with acute appendicitis there was no place for procrastination. It was absolutely impossible to foretell which cases would do well without operation, and which would prove fatal without operation. In acute appendicitis the symptoms were so deceptive, the physical signs so inconstant, the indications of danger so slight, the ultimate issue so uncertain, that immediate operation as soon as the diagnosis was made was the wisest course, and would enable us to approach within measurable distance of the ideal expressed by Dr. Murphy, "We ought to have no deaths from appendicitis."

Tuberculous Mesenteric Glands and Some Abdominal Conditions They May Give Rise To.—Mr. G. P. NEWBOLT of Liverpool read this paper. These glands might give rise to acute abdominal crises of which volvulus and acute peritonitis due to the rupture of a suppurating gland were the best examples. In addition, various subacute, or chronic conditions might occur, giving rise to pain simulating appendicitis, etc., which needed surgical interference. The conditions were chiefly met with in young adults. Whenever the glands were so much enlarged as to be palpable, and when, in addition, they gave rise to pain, they should be removed in order to get rid of a condition which might terminate in an acute emergency. When met with in the course of abdominal operations, and when caseating, they should be removed, unless this involved risk to the patient, in which case one should wait and interfere later, if necessary. It was well to remember that these glands might give rise to trouble, when consulting the causes of abdominal disease.

Treatment of Cleft Palate.—Mr. JAMES BERRY of London presented a table of 81 consecutive cases of cleft palate treated by operation. In 37 cases of complete cleft of hard and soft palate he had obtained complete union after the first operation in 15, and after a supplementary operation in 7. In 22 cases of cleft of soft and part of hard palate complete union had been obtained in 12 after the first operation, and in 5 after one or more supplementary operations. In 21 cases of cleft of the soft palate only complete union was obtained after the first operation in 17. In one case of central cleft of the hard palate only operation had resulted in partial closure.

Fibromatous Tumors of Mesentery.—W. J. GREER of Newport stated that early records contained references to mesenteric tumors found at autopsy in women who had been thought to be pregnant. As to their etiology little was known. The diagnosis was difficult and errors were frequent. The tumors developed sometimes painlessly, but usually causing constipation and discomfort. Abdominal examination revealed areas of dullness surrounded by areas of resonance with the tumor more movable in the transverse direction than in the vertical. The prognosis was unfavorable if operation was not performed. The operation consisted in careful enucleation, with closure of the cavity with catgut. Resection of a portion of gut might be required. The speaker reported a case of successful removal of a mesenteric fibromatous tumor weighing 3 pounds and 4½ ounces.

Fracture of Scaphoid Bone.—W. A. MACLENNON of Glasgow read a paper on this subject.

(To be continued.)

AMERICAN PEDIATRIC SOCIETY.

Twenty-third Annual Meeting, Held at Mohonk Lake, N. Y., May 31-June 1, 1911.

THE PRESIDENT, DR. HENRY DWIGHT CHAPIN OF NEW YORK, IN THE CHAIR.

(Continued from page 253.)

The Value of Pertussis Vaccine in the Treatment of Whooping Cough.—Dr. EDWIN E. GRAHAM of Philadelphia read this paper. He said that the fact that pertussis in infants was such a serious disease and that it had a tendency to be complicated by pneumonia, emphysema, convulsions, and perhaps paralysis, together with the fact that it did not respond to treatment by drugs, made it important that any new treatment that offered a reasonable hope of success should be thoroughly tested. Bordet and Gengou claimed to have found the bacillus of pertussis and described it. This bacillus did not grow well in blood agar but developed in liquid media of one per cent. glycerinated bouillon with equal parts of rabbit's blood or serum. In his earliest cases Dr. Graham gave 20,000,000 bacteria for four days. This dose did not produce any untoward symptoms and was increased to 40,000,000 bacteria every four days. A careful study of these cases seemed to show that the disease was modified by the treatment employed. The same dose was then given every three days and later every two days, the number of injections varying from six to eight. In not a single instance was there any evidence of any local reaction. Those who came into intimate contact with these patients had been in favor of the remedy, believing that it diminished the number and severity of the attacks and shortened the course of the disease. Only 24 cases were reported; of these seven were apparently not benefited by the treatment. Dr. Graham believed that the dose should be increased beyond 40,000,000 especially in severe cases.

The results obtained in these cases warranted a more extensive trial of the vaccine.

An Operation Upon Tonsils and Adenoids.—Dr. Charles Gilmore Kerley of New York presented this paper, in which he stated that during the past year he had performed adenoid and tonsil operations 371 times. The method of procedure until eighteen months ago was to remove as much of the tonsil as possible by firm pressure with the tonsillotome. In this way from two-thirds to seven-eighths of the tonsil was removed. The majority of cases seen early were permanently benefited to some degree, while in others the benefit was only temporary, the tonsil soon resuming its former size. A second and sometimes even a third operation had been required in many cases. Dr. Kerley had for some time appreciated the desirablity of the complete removal of the tonsil. He learned of the method of finger enucleation practised by Dr. Frank S. Mathews of New York City (*Annals of Surgery*, December, 1908) and had followed that procedure with but little deviation. Anesthesia was administered to the point of the abolition of the corneal reflex. The object was to strip the tonsil from its bed. In operating upon the right tonsil he passed the index finger into the mouth and with moderate pressure the finger was passed into the superior fossa at the junction of the anterior and posterior pillars. He then went above the tonsil and worked down behind the capsule, pulling the tonsil downward; with pressure exerted first anteriorly and then posteriorly he separated it from its attachments until it hung by a pedicle. The tonsillotome was slipped over this pedicle. Pressure was made from without by the anesthetist and from within by the operator and the pedicle was cut. He had no difficulty in removing the whole tonsil by this method. Tonsils deeply imbedded slipped out as easily as those more superficially placed. The duration of the entire operation was rarely more than six minutes, and this included as well the removal of any adenoids that might be present. In the removal of adenoids he used the modified Gottstein curette built on an angle of about 45 degrees. From six weeks to three months after operation the nasal vault was examined for adhesions and if any were present they were easily removed with the finger.

Dr. Rotch of Boston thought that Dr. Kerley's paper had brought up a number of valuable ideas. They should remember in considering the subject of tonsils in children that the process of development must be taken into account. Normally adenoid tissue occurred up to a certain age and then tended to diminish. This fact accounted for the recurrences when early removal was practised. He did not know whether this radical enucleation put an end to normal growth or not, but if they operated later there was not much tendency to recurrence. Again it was not always the enlarged tonsil that gave the most trouble; absorption from a small amount of diseased tonsil affected the health of the individual. Tonsils that were not enlarged frequently had to be removed for this reason.

Dr. L. E. LaFetra of New York said that he had had a talk with Dr. Mathews when the latter was working out the technique of his operation and the latter had showed tonsils that had been removed by this method; ever since it had appealed to the speaker as the most satisfactory method. With this procedure there need not be any fear of recurrence. Another point was that they did not see the severe attacks of sore throat that they did when the tonsils were simply sliced off. There were cases in which the separation of the tonsillar pillars from the tonsil was very difficult because of repeated attacks of inflammation, and the use of separators would be found necessary in more cases than Dr. Kerley's paper would indicate. If one operated upon a child of six or seven years who had had frequent attacks, the capsule would be found adherent and if one tried to enucleate the tonsil with the finger alone there would be the same bleeding that occurred when the tonsil was sliced off. There was also some danger of tearing the tonsillar pillars. The speaker had found that in using the adenoid curette it was better to use it as one would a knife, making a lateral motion and cutting across the base of the adenoid so that it was removed in one piece. This was more satisfactory than making two or three sweeps with it as in using a curette. Of course the curette should be very sharp.

Dr. Henry Koplik of New York said that the cases that had been operated upon two or three times and had recurrences were very discouraging. Some of them still had obstructions in the nose and postpharyngeal space. It was an obstruction not due to adenoids alone, but to a thickening of the whole mucous membrane and to adenoid tissue under the mucous membrane. Repeated operations really harmed this particular class of children. The whole subject was not as simple as it had appeared to be here this morning. Some of the cases required a great deal of consideration as to when operation should be done and as to whether any benefit might be expected from operative procedures. There were other forms of tonsils which operators seemed anxious to remove, as for instance the small tonsils in babies just born. Dr. Koplik had seen several of these cases operated upon in which it seemed that the condition of the child was worse after the operation than before. This did not refer to cases where diseased tonsils were causing trouble. He felt that tonsils had been placed there for some purpose and future study might reveal this. With laryngologists who had given the subject the most study the tendency was to leave a small amount of tonsillar tissue behind. The speaker had seen two cases of endocarditis following enucleation and in the hospital others had seen similar cases. He had also seen severe diphtheria occur on the seat of a tonsillar fossa.

Dr. R. G. Freeman of New York thought that if they looked at the tonsils as a part of the normal mechanism for keeping out bacterial infection it was a question whether they should be entirely removed. If they should not be removed then they might expect after their removal to see an infection of the cervical lymphnodes. Dr. Kerley had mentioned such a case. It was questionable if it was not better to leave some of this tissue.

Dr. Haines of New York thought that enucleation was better than cutting, because of its simplicity and freedom from hemorrhage and subsequent prostration. It seemed to him that the cases in which the hemorrhage had been greatest were those in which sharp instruments had been used. The use of calcium lactate had in his experience lessened hemorrhage. He believed that so far as the adenoid was concerned the curette was all that was required except where the tissue was so far forward that it was in apposition with the vomer. The removal of the entire adenoid in one piece was preferable. It was advisable to feel with the finger in the postnasal space and to guide the blade of the curette.

Dr. J. Mason Knox of Baltimore asked Dr. Kerley what the age was of the children upon whom he operated and what he considered the indications for removal of adenoids in babies. He also asked whether the results had been as good in babies as in older children.

Dr. Henry D. Chapin of New York called attention to the fact that in some children the bony pharynx was shaped like a Gothic arch instead of a round one and in his experience such children did not get as much relief from the adenoid operation as did others. Some symptoms that were attributed to adenoids were really due to an underlying condition of faulty development. Tonsils probably had some function to perform; it might be

that of producing an internal secretion and some harm might result from their complete removal.

Dr. Jacobi of New York said that he had been told that this operation was a difficult one and that cases should be sent to the author of it for operation; he was glad to learn now that there was no longer a monopoly in this field and that this operation was very easily performed. He did not believe, however, that it should be done as frequently as some gentlemen seemed to think. It was not a matter of indifference whether the capsule was removed or not. He believed that we should learn that infection through the capsule was rather difficult; the capsule was a protection to the blood and lymph circulation. It was probable that the infection of rheumatism and scarlet fever through the capsule was not so frequent; it more likely took place through the soft lymphnodes of the Waldeyer ring. Dr. Jacobi emphasized the desirability of keeping the nares clean both before and after operation; if there was greater care in this respect so many operations would probably not be necessary. The speaker also advocated irrigations rather than injections.

Dr. Kerley of New York, in closing the discussion, said that Dr. Haine's point was an excellent one, namely, that of locating the adenoid with the finger in the post-nasal space at the time of using the curette. As to the age of the patients, he tried to avoid operating upon children under one year of age. This was especially true so far as the tonsils are concerned. However, he thought that adenoids should be removed regardless of age if they were sufficient to produce obstruction. As to the endocarditis to which Dr. Koplik referred, there were many cases of this condition where tonsillectomy had not been performed and how could he tell whether the endocarditis was due to the tonsillectomy? The laryngologist was perhaps not always a safe man to follow, as he did the operation and then turned the case over to the pediatrist. He thought the use of the pillar separators a very good thing. As to the function of the tonsils he knew nothing, but he did know that the ones he took out were so riddled with holes and filled with connective tissue and crypts filled with bacteria that they failed to perform any function if they had one. Adenoids did return, but there was no reason why they should not be removed a second or a third time if necessary.

Thursday, June 1—Second Day.

The Polygraph as an Aid to Diagnosis in Cardiac Conditions in Children.—Dr. Godfrey R. Pisek and Dr. T. Homer Coffen of New York presented this paper. They said that the use of the polygraph had proven of great value in correlating physiological and clinical data in adults. Polygraphic records had stimulated closer study of the heart and circulation and newer conceptions of the intricate heart mechanisms had been developed. This method gave precise knowledge of cardiac functions and could be compared with the data obtained by the pathologist in his laboratory. The authors undertook to discover whether satisfactory tracings could be made from children, if additional information could be obtained in physical examination, and if this information could be made practical in prognosis and treatment. With slight modifications of the apparatus and technique they were able to make records in children without any difficulty. They gave an analysis of their findings, showing their significance in such conditions as heart block, cardiac arrhythmia, and the extra heart sound, and concluded that when making a physical examination of the patient with cardiac disease perhaps the least important factor was the determination of the precise valve involved. It was more important to determine the exact power of the heart, the functionating ability of the myocardium, and the data of the cardiac activity. Polygraphs would not stultify physical findings, but would enhance their value.

Dr. L. E. La Fetra of New York reported a case of heart block occurring in a child eight years old. The polygraph showed that she had partial heart block, with two auricular systoles to one ventricular; the auricular 80 to the minute and the ventricular 40. In seeking the possible cause of this condition it was found that the patient had had diphtheria three years before, with some paralysis, and it was possible that this caused some disturbance of the bundle of His, preventing complete conduction. One similar case had been reported.

Dr. Jacobi of New York thought that for a long time they had neglected the diseases of the myocardium. These had been conceded to be an important factor only within the past twenty-five or thirty years. He feared that now they were in danger of overdoing it. Formerly they made only a diagnosis of endocarditis; now they made only a diagnosis of myocarditis. They had learned that in chronic aortic disease digitalis and strophanthus would do little for them and were contraindicated, and if the myocardium was so absolutely the prevailing factor in their indications they might be led into error.

Dr. Pisek of New York said he was glad Dr. Jacobi had brought out that point. Before making any exact reports the study should be continued for a year or two, especially in diphtheria and scarlet fever, where they had found in checking up the diagnoses that they could determine that there was no obstruction in the conductivity or in the essential functions of the heart. A great many cases of accidental murmur had been recorded as grave conditions, and in this way they could check that up.

A Preparatory Study of the Bacillus Acidophilus in Regard to Its Possible Therapeutic Use.—Dr. Thomas Morgan Rotch of Boston read this paper, in which he stated that recent advances in their knowledge of the gastroenteric tract had been so great that it seemed to be time to begin studies as to the practical use which they could make of individual organisms. Prominent among these organisms was the *Bacillus acidophilus*. This bacillus was a hydrocarbon saprophyte. It did not produce toxins. It was a fermental organism whose habitat was in the large intestine. It throve on carbohydrates and produced relatively large amounts of lactic acid from fermentable sugars. It was antagonistic to the proteolytic organisms, producing fermentation provided sugar was present. Although it produced acid it grew best where the medium was less acid. It appeared to grow better below the ileocecal valve than above. The *Bacillus acidophilus* was non-pathogenic for experimental animals and under normal conditions was found to be the inhabitant of the intestinal tract of man. It had the ability to render that portion of the intestinal tract where it was located unfavorable to the development of other invading organisms. It might form a considerable amount of acid from carbohydrates, this occurring mostly below the ileocecal valve. The *Bacillus bulgaricus* had some different characteristics; its habitat was chiefly above the ileocecal valve, and it grew less as it approached the anus. There appeared to be a considerable number of intestinal disturbances associated with the activities of the putrefactive bacteria, some of which might be influenced by the activity of the *Bacillus acidophilus*. There were three types of bacterial activity recognized in the intestinal tract, the proteolytic, the fermentative, and the facultative. The intestinal bacteria of abnormal nurslings were strictly fermentative. It had not been proven that the fermentative flora of the normal nurslings was a valuable factor in protecting the host from invasion by other organisms, particularly of the proteolytic type. It was evident that the increased administration of carbohydrates and the restitution of the protein would furnish the dietetic conditions most favorable for the development of the proper organisms; if the obligate fermentative bacteria were present and available in the intestinal canal they might be brought

up to their natural degree of activity. The observations presented were designed to show the feasibility of encouraging the growth of the *Bacillus acidophilus* by a suitably modified food. From a theoretical point of view it seemed advisable to introduce cultures of *Bacillus acidophilus* provided they were known to have been obtained from a source known to be normal and apparently free from objectionable conditions. The speaker described the details of his experiments and gave a complete report of two cases.

Dr. L. Lovett Morse of Boston said that he had understood Dr. Rotch to say that the acid reaction of the stool was due to the sugar in the food; he thought it depended upon the relation of the fats and proteids and that the sugar had no effect.

Dr. Jacobi of New York said he had a prejudice against this bacillus because of its name; it had a long Latin name with a good-sized Greek termination and he would suggest that Dr. Rotch should act as godfather and give it a better name. As to the use of these bacteria as a medicine he was glad if there was something that he could give to correct the mistakes of nurses and doctors. If they insisted on feeding babies on an exclusive milk diet they would have this condition. By adding carbohydrates to the food the condition would not be created. All these scientific researches confirmed what he had insisted upon for half a century, namely, that they should not feed milk without carbohydrates. Cane sugar or cereals should be substituted for the too plentiful milk diet.

Dr. J. Mason Knox of Baltimore thought that as far as the treatment of dysentery was concerned the reader of the paper took a rather too optimistic view. The bacteria were located in the mucous membrane after the onset of the disease and were in intimate association with the lymph and blood, and it was not likely that feeding different kinds of bacteria in ulcerated dysentery would give very brilliant results.

Dr. Charles Hunter Dunn of Boston related that during last summer an attempt was made to treat these cases by injections of sterilized dextrose solution into the blood. The cases were as yet two few to enable them to draw conclusions, but it was thought that there was some amelioration of the condition. It seemed to the speaker that the great difficulty lay in getting the proper diagnostic basis. They had probably been using acid producing bacilli in fermentative conditions without such a clear knowledge as they now possessed of the difference between fermentation and putrefaction. What was needed was a simple method of making the diagnosis.

Dr. Rotch of Boston said that Dr. Knox was right in what he said about dysentery; they could not reach the organisms after they had penetrated the mucosa. The organisms produced toxins in the intestines, however, and they reduced the number of bacilli which were making toxins. In regard to Dr. Morse's remarks, the speaker said that it was a well accepted fact that carbohydrates and sugars did produce acid and that changes in the diet brought about a change in the condition, a change which was inimical to the putrefaction.

(To be continued.)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

237th Regular Meeting, February 3, 1911.

The President, Dr. H. M. Biggs, in the Chair.

On the Control of Hemorrhage from Neoplasms of the Bladder, with Remarks on the Trypsin and Ascitic Serum (Hodenpyl) Treatment.—By Dr. L. B. Bangs. (See page 359.)

Dr. C. L. Gibson said that the case reported by Dr. Bangs as having received the Hodenpyl serum had already been commented on by another speaker while reviewing the treatment in a case which seemed to show amelioration. Dr. Samuel Alexander also related a similar experience, but the patients promptly died. The apparent changes for the better in such conditions might be explained thus: carcinoma was a parasitic condition, and was influenced by the condition of the parent trunk. Introducing a foreign material like serum into the circulation produced changes which were sometimes quite obvious in the recipient, lowering his vitality and secondarily that of its parasite, the carcinomatous growth. The Hodenpyl treatment, Dr. Gibson further stated, was erroneously conceived on an impression that the serum was derived from a case of spontaneous healing of a carcinoma: later this belief was demonstrated to be false.

Dr. V. P. Gibney asked Dr. Bangs if there had been any permanent cures by means of the Hodenpyl serum. He had heard that there were and also that there there none.

Dr. L. B. Bangs, replying to the question, said that it was the statement of its effect upon external and visible tumors that led him to make the experiment, but he did not know of any real cures by this serum. However he felt justified in making the attempt. He could not say that the course of the malady had been changed any, except apparently a sudden increase in the size of the obstruction, which he could not explain scientifically for the reason that an autopsy could not be had ,and, therefore, he did not know the exact size after the treatment had been ended.

An Unusual Duodenal Ulcer.—Dr. W. Gilman Thompson reported this interesting case, and stated that it was unusual from its long duration, with exceedingly serious hemorrhages, and the possible etiology. The patient was a robust man, now 52 years of age, who for twenty-five years had suffered from occasional sudden attacks developing three or four hours after eating, and consisting of intense nausea, cold sweats, great prostration, and subsequent vomiting of blood and its passage in the stools. True pain and epigastric tenderness were not complained of, but there was a sensation of vague epigastric discomfort, which the patient had described as a sensation of obstruction, "as if some greasy, ill-tasting substance had been eaten." The earlier attacks were attributed by the patient to biliousness, as blood was observed only in minute quantity, but at the age of 47, and again at 49, hematemesis twice occurred in such severity as to produce partial coma and bring life to the lowest possible ebb. The speaker saw the man in both of these attacks, and in several minor ones, and in one of them he sought surgical aid, but in the opinion of the surgeon the man was moribund, and the operation was not justified. The worst attack occurred in the midst of a dinner at the house of a friend, when the patient suddenly became deadly pale and faint, but without pain or local tenderness. He reached his home in a cab, and was then attacked with hematemesis and melena. He also recovered with astonishing promptness from the attacks, and, being abstemious as to both food and drink, remained in robust health in the intervals. This fact, together with the long duration of the malady, led the speaker to the suspicion that the hemorrhage might be due to some unusual local vascular condition in the intestine. On examining the abdomen he found an elevated bunch of congenital varicose veins, about three-fourths of an inch in diameter, situated a short distance above the umbilicus, and it seemed possible that there might have been a similar defect in the veins of the duodenum, one of which, when irritated by food, occasionally ruptured. With this provisional diagnosis the patient was sent to Dr. William J. Mayo for exploration in an interval when he was in good health. Dr. Mayo's report, which was written two years ago, stated: "Judge X was operated

upon this morning. We found a varicose ulcer on the superior wall of the duodenum, one and one-fourth inches below the pylorous, which had a chronic perforation, that is a point where it was closely adherent to the edge of the lesser omentum and gall-bladder, and which, when separated, left a small opening into the duodenum. The ulcer was small without much induration except at the adherent point, and, while there was considerable contraction, there was no obstruction. The ulcer was enfolded and the vessels closed with mattress sutures of linen." In the two years which had elapsed since the operation the patient had remained in perfect health, the speaker said, without digestive disorder of any kind. The connection between the varicose veins of the abdominal wall and their presence in the intestine, Dr. Thompson said, suggested the hypothesis that both were congenital vascular defects, and that such may occasionally be a factor in the obscure etiology of duodenal ulcer.

Two Cases of Malignant Tumor of the Orbit, Treated by the X-Ray, with Very Different Results.—Dr. C. S. Bull reported these two cases. The first was that of a gentleman, aged 46, who was first seen in January, 1900. The left eye was displaced upward and slightly outward, and the lower lid was pushed forward by a growth which occupied the inferior orbital margin and extended back along the floor of the orbit, mainly to the nasal side. After careful examination of the nose and pharynx, and the use of transillumination, the speaker decided that the superior nasal meatus and the ethmoid antrum were not involved, and that it was purely an orbital growth, and he decided to operate. The growth was removed from the margin and floor of the orbit, leaving the eye in place. The periosteum was stripped from the lower margin of the orbit and floor as far back as could be reached. The maxillary antrum was not involved, and there was no opening into the nasal meatus and none in the orbital plate of the ethmoid. The orbital tissue did not seem to be involved, and the speaker concluded that the growth had started from the periosteum of the floor. The patient made a rapid recovery and the eye resumed its normal position with vision of 20/40+. The patient remained free from any return of the growth for about two years and a half, and then a nodule was noticed at the inner angle of the orbit, which grew rapidly and extended into the orbit and lower lid. When he saw him four months later the whole orbit was involved, the eye protruded forward, outward and upward, and the maxillary antrum and ethmoid by transillumination were found to be involved. The patient was told that nothing but a very radical operation, including the resection of the superior maxilla and cleaning out the entire contents of the orbit, ethnoid, and superior nasal meatus, would do any good. To this he consented. When the orbit was cleaned out there was such a profuse and continuous hemorrhage that a consultation of the physicians present advised ligation of the left common carotid, which was done. All the diseased bones were removed, including the contents of the ethmoid. The frontal sinus was not involved. The patient made a slow but uneventful recovery, and, while the cheek was sunken, the deformity was not as great as had been feared. He remained perfectly well for nearly three years, and then a recurrence appeared at the inner canthus and lower lid and jaw with great rapidity, so that in two months there was a large bulging mass protruding from between the lids. Dr. Bull advised against any further operative interference, and suggested that treatment by *x*-ray be tried, which was done. The patient had eighteen sittings of varying length and at varying intervals, covering a period of four months. At that time all traces of the neoplasm had entirely disappeared, and there had been no return of the growth for a period now of about three years. The original tumor and the recurring growths proved to be sarcoma of the round cell type.

Dr. Bull's second case was that of a young man, aged 26, whom he saw in January, 1906. Three years before he noticed a protrusion or swelling at the upper and outer angle of the left orbit, which slowly but steadily increased in size, and of late it had been quite painful. There was partial ptosis, and the eye protruded forward and inward toward the nasal side. There was some limitation of motility outward and upward. There was some chemosis of the conjunctiva and constant pain, which was increased by any pressure on the lid and eyeball. The growth showed at the external canthus, where it was ulcerated and bleeding. About three months before the speaker saw him a similar swelling had appeared at the upper and outer angle of the right orbit, and had increased rapidly in size. A careful examination convinced Dr. Bull that he had to do with a neoplasm of both lacrymal glands, and his first suspicion was that it was tuberculous. A cutaneous and a hypodermic test with tuberculin were made on two occasions, but the result was negative, and there was no reaction. There was nothing in the personal or family history to point to a tuberculous origin. He then decided that it was probably a sarcoma of the lacrymal gland, and he proposed that he should try the treatment by the *x*-ray. The patient had twelve exposures at intervals of three days apart, the exposures varying in time from three minutes to twenty minutes. The effect of the treatment was quite unexpected, as there was a steady increase in the growth at a much more rapid rate than before with corresponding increase in the pain. After the twelfth exposure the speaker concluded to attempt the removal of the tumors. An incision was made through the upper lids just below the orbital margin, and both glands were removed, after careful dissection from the underlying periosteum, the adhesions not being very serious except at the extreme upper end of the glands. A careful examination was then made of the orbits, but nothing of the nature of infiltration of the orbital tissue or extension of the growth was found. The patient made a rapid recovery, with complete motility and perfect vision and disappearance of the ptosis. A microscopical examination of the tumors showed them to be sarcoma of the small round cell type, but with very marked hypertrophy of the connective tissue structure of the glands.

Dr. L. B. Bangs asked Dr. Bull if radium had been used.

Dr. Bull replied that the first case occurred before there was any knowledge of radium as a therapeutic agent, and that the second case was about five years ago, and then radium was not procurable. Just before the operation he had asked the patient to have radium applied, but the latter had declined to have any further experimenting except with the knife. In addition to what he had already said the speaker added that the sarcoma had involved the sinus. If the tumor was encapsulated Dr. Bull said that the operation would be successful, with the possibility of no recurrence, but if it had broken into the orbit or involved the sinuses secondarily, any operation, no matter how radical, for removal caused a very rapid recurrence of the growth. This was based on an experience of 463 cases.

Dr. Joseph D. Bryant said that if the removal was incomplete it was a very active source of returning and that there was not much change to be noted in that location.

Recurrent Carcinoma of the Bladder.—Dr. C. L. Gibson presented a bladder removed post mortem with the following history. The patient had been operated on

by Dr. Keyes, Sr., for a so-called villous tumor of the bladder. From this he had recovered and had been free from any trouble for more than nine years. He was seen then by Dr. Gibson greatly exsanguinated with a palpable mass in the bladder and passing pure blood. No attempt was made at cystoscopy. A suprapubic cystotomy was performed, and the bladder was found to be filled with diffuse masses as big as the fist involving apparently all parts of it. These were removed as much as possible simply to give a little more space. A microscopical examination showed that it was an epithelioma. The wound healed entirely and there was no recurrence of the hematuria; he was passing clear urine and the bladder held as much as a pint. One would not know that he had anything the matter with his bladder. The patient was then lost sight of for a period of five years, during which he was able to work and earn his living. At the end of this period he came back, saying that he had been bleeding for a few weeks past. His hemoglobin was only 10 per cent. and he died. The bladder showed now only two nodules of the carcinoma as big as a cherry.

Dr. L. B. Bangs said that Dr. Gibson's case was quite in line with a similar experience of his own, but which was not as remarkable as the one reported. He concurred in the statement as to benign papilloma and further stated that he had had only one experience in the removal of a papilloma in which the recurrence had also been a papilloma.

Philadelphia Pediatric Society.

At a stated meeting held March 14 Dr. E. B. Hodge presented kidneys from a child exhibited before the Society on several previous occasions and upon whom the operation of decapsulation of the kidneys was twice performed. In the first illness the child presented symptoms of acute nephritis and a fatal issue appeared imminent. Following the operation the patient improved, and she remained in comparative health for a period of two years, although edema was readily induced by slight disturbing influences. The second operation was performed on the supervention of grave phenomena, but the patient failed to respond. The kidneys were found enclosed in their fatty capsules, but there had been no restoration of the fibrous capsule. Dr. Harry Lowenburg demonstrated a boy who had presented symptoms of intracranial pressure from which he had recovered. He was seven years old, and his head had been enlarged from birth. He developed headache, vomiting, and optic neuritis, and the symptoms disappeared under administration of potassium iodide and mercuric chloride gr. 1/24 thrice daily. The condition was looked upon as internal hydrocephalus. Dr. Robert S. McCombs reported "A Case of Anterior Poliomyelitis Occurring at Five Months of Age, Associated with Facial Palsy." The little patient was seized with fever and diarrhea and presented paralysis of the left upper extremity, of the left side of the face, and of the movements of muscles controlled by the third nerve. Dr. T. H. Weisenburg presented specimens of brain tumors occurring in children and he discussed their clinical significance. He pointed out the rarity of intracranial tumors in early life and their ease of diagnosis in some instances and the difficulty in others. He demonstrated a specimen of a growth in the cerebellopontine angle, one in the third ventricle, one in the cerebellum, and others. Drs. S. S. Woody and J. A. Kozmer presented a communication entitled "A Study of Non-Diphtheritic Exudates." They pointed out the difficulty in determining the nature of a lesion of the mouth and pharynx merely from the clinical manifestations. They considered in detail, in contrast with the exudate and other phenomena of diphtheria, these observed in connection with Vincent's angina, and with pneumococcic, streptococcic, and staphylococcic infections.

Medicolegal Notes.

Liability of Hospitals for Malpractice.—Hospitals treating patients for hire are generally responsible for the negligence or malpractice of their physicians; hospitals conducted for charity, on the other hand, are not. A suit was brought by the administration of a railroad employee against the railroad company for wrongful death caused, it was alleged, by failure to furnish proper medical and surgical attention after an injury. It appeared that a monthly hospital fee was deducted from the pay of the railroad employees to maintain a hospital for them when occasion required. After an injury to the deceased he died, after being treated in the hospital. The railroad company derived no profit from its hospital department. It was held that the railroad company was a mere trustee to administer the hospital fund, and was responsible only for ordinary and reasonable care in the selection of competent and skillful physicians and attendants, and was not liable for the negligence or malpractice of physicians employed by the department.—Arkansas Midland R. Co. v. Pearson, Arkansas Supreme Court, 133 S. W. 917.

Competency of Medical Testimony as to Composition of Gallstones.—In an action to cancel and revoke a license to practise medicine on account of "grossly unprofessional and dishonorable conduct of a character likely to deceive or defraud the public," under the Texas statute of 1907 (Gen. Laws, pp. 224-228), it appeared that the defendant gave himself out as a specialist in the cure of gallstones. He gave a patient medicine composed principally, if not entirely, of olive oil, which she took, and passed from her stomach and intestines a large number of balls, of a green color, from one-eighth to three-eighths of an inch in diameter, which the defendant examined and pronounced to be gallstones, knowing that they were not. It was held that the act was not invalid because it failed to define what was grossly unprofessional or dishonorable conduct. To an objection to the evidence of regular physicians because of the difference of the mode of treatment of diseases by the various schools, defendant claiming to belong to the eclectic school, the court held that the former could testify to questions of anatomy for or against a member of any other school. Regarding the particular point in issue it did not take the wisdom and lore of an allopath, the knowledge of a homeopath, the philosophy of an eclectic, or the erudition of an osteopath to fit a man to testify to the chemical elements composing the balls. Any chemist of any school of medicine could testify to their composition; any one from whatever school could testify that a canal or duct the size of a small pea could not form a passage for a stone the size of a hen's egg.—Berry v. State, Texas Court of Civil Appeals, 135 S. W. 631.

Hospital Records as Evidence.—In a contested will case, where most of the medical evidence was furnished by the physicians attached to hospitals, certain hospital records were allowed to be used in the course of examination by the physicians who made them to refresh their recollection, in accordance with the rule that, where shown to be true at the time made and that the witness has no independent recollection of the facts, a memorandum itself may be given in evidence. But the hospital records themselves, not being public documents, were held not to be receivable as evidence of the facts therein stated. *In re* Hock's Will, 129 N. Y. Supp. 196.

Reading Medical Works to Medical Expert.—It is sometimes the custom in will contests, where the testamentary capacity of the maker is in question, to read from medical books written by eminent physicians, and ask, on cross-examination of a medical expert, whether or not authors whom the witness admitted to be good authority have not expressed opinions different from that given on the stand. In such cases the reference is not for the purpose of making the statements in the books evidence before a jury, but solely for the purpose of ascertaining the weight to be given to the testimony of the witness. The extent to which such examination may go has been held discretionary with the court, and there is no well founded objection to it. But the established rule is that a party cannot read from medical works and ask his expert if he agrees with the statements of the author or if it accords with his experience. The distinction is narrow. In such a case, therefore, all the answers of the experts on cross-examination which were to the effect that they agreed with the statements of medical authors read to them by the cross-examiner were struck out. When the answers were to the effect that the expert witness did not agree with the particular authors read to him the answers were allowed to stand; but permission was given to recall the medical witness, if counsel so elected. While the ruling is in

line with the authorities the result may not be quite fair to the examiner, who is bound by unfavorable answers and gets no advantage of the favorable answers of the expert. *In re* Hock's Will, 129 N. Y. Supp. 203.

Duty to File Certificates of Birth.—A physician who fails to file a certificate of birth within ten days, as required by the Greater New York Charter (Laws 1901, c. 466) § 1239, is liable to the penalty imposed by the statute unless the omission is excused by the commission of health, though the child lives but a short time and the physician files a certificate of death which gives the date of the birth. Department of Health of City of New York v. Dunn, 129 N. Y. Supp. 29.

What Constitutes a Consultation?—"Talking with" a physician and getting medicine from him, it is held, is equivalent to a consultation. Why, said a Missouri court in an insurance case, should a layman talk with a physician about his health and get medicine from him except it be with a view of obtaining direction, information, or advice as to his health, and, if he did that, he was consulting with him. The layman and the physician are not on terms of equality on the subject of the health of the layman, and, where a talk on that subject is accompanied by the giving of medicine by the physician to the layman, the inference is irresistible that the "talk" was a consultation. Winn v. Modern Woodmen (Md.), 137 S. W. 292.

Masseur Treatment Practising Medicine: Constitutionality of Statute Requiring Certificate on Examination.—In an appeal from a conviction of a masseur of the offense of practising medicine and treating disease without registering a certificate the defendant contended that any man has a right to treat disease by the masseur treatment and charge therefor without procuring a certificate or license from the State medical board. The Texas statute, Acts 30th, Ly. c. 123, provides that it shall be unlawful for any person to practise medicine in any of its branches without obtaining such a certificate, to obtain which a man must be examined as to his knowledge of various medical subjects. It provides that any person shall be regarded as practising medicine who publicly professes to be a physician or surgeon and treats or offers to treat any disease or disorder by any system or method, or to effect cures thereof, or who shall do so and charge therefor, directly or indirectly. It was held that this statute was not unconstitutional as discriminating against the practice of the masseur treatment. It did not attempt to say how any one should treat disease. All it said was that he should have a knowledge of certain given subjects before he should undertake to practise. There was no error in not permitting the defendant to prove that there was no board where he could obtain license to practise massage. There was a board where he could obtain such a license; but he must show, in order to get that license, that he had a knowledge of the human anatomy, was able to diagnose disease, and had a knowledge of the studies prescribed. The person named in the information was treated by the defendant for appendicitis. The prosecution was allowed to prove that the defendant treated other persons also, that he had issued advertisments for the purpose of obtaining practice, and the nature of these advertisements, that he made representations to the father of the person named in the information and to others that he could cure appendicitis and certain other diseases and had done so. Evidence as to whether the treatment given by defendant was harmful or beneficial was not material to the case, nor was evidence as to whether the person named in the information had been treated by others before she was treated by the defendant. Germany v. State, Texas Court of Criminal Appeals, 137 S. W. 130.

Evidence: Refreshing Recollection.—In an insurance case a physician's day-book was in evidence before the jury. On the physician's examination the court refused to allow him to refresh his memory as to the date of certain treatments from an *ex parte* affidavit previously made by him. There was no prejudicial error in this, as the witness accomplished the same thing by stating that all his entries were entered in the day-book. Winn v. Modern Woodmen of America, (Mo.) 137 S. W. 292.

Construction of Statute Against Prescribing Intoxicating Liquors.—The Louisiana Act 85 of 1886, page 124, makes it a crime for any physician to prescribe intoxicating liquors with intent to evade or assist others in evading the intoxicating liquor laws of the State. The act applies both to prohibition territory and to territory where the sale of intoxicating liquors is allowed on payment of a license, making it in the latter territory a crime for a physician to prescribe intoxicating liquors with intent to evade or assist others in evading the law requiring a license. State v. Terry, Louisiana Supreme Court, 55 So. 15.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended August 12, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	424	159
Diphtheria	208	18
Measles	172	13
Scarlet Fever	66	1
Smallpox	—	—
Varicella	20	—
Typhoid Fever	157	14
Whooping Cough	88	9
Cerebrospinal Meningitis	5	8
Malarial Fever	—	—
Totals	1,140	222

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended August 11, 1911:

Places	Date	Cases	Deaths
CHOLERA			
Austria-Hungary: Trieste	Aug. 1–7	22	2
Bulgaria: Kalondjik	June 18–20	1	1
Vicinity of Choumen. From the ship Cyrille, bound from the coast of Asia Minor.			
Ceylon: Colombo	June 19–24	3	2
France: Marseille	Aug. 8–10	6	2
Greece: Piraeus, quarantine station	Aug. 4		Present
Italy			
Total for all Italy July 16–26: Cases, 1,018; deaths, 429. Continental Italy outside of Naples Province, July 16–26: Cases 215; deaths, 86.			
Provinces—Naples	July 16–26	303	130
Naples	July 16–26	155	38
Palermo	July 22–26	75	35
Palermo	July 16–26	238	130
Sicily			
Outside Palermo Province, July 22–26: Cases, 32; deaths, 10.			
India: Bombay	June 25–July 1	3	3
Calcutta	June 4–17		93
Madras	June 12–18	1	1
Rangoon	May 1–31	16	15
Indo-China: Saigon	June 12–25	10	10
Java: Batavia	June 19–24	28	10
1 European.			
Russia			
New outbreak Apr. 21–July 10. Cases, 29; deaths, 4, including 7 cases and 2 deaths, p. 1044, vol. 1.			
Governments: Baku—Baku	July 8	1	
Khasan—Kosmodemiansk	July 2	1	
Kherson—Nikolaiev	July 9–10	3	
Samara—Nikolayevsk	June 29–July 3	15	1
Vitebsk—Lepel district	June 19	1	1
Straits Settlements: Singapore	June 4–17	16	22
Turkey: Constantinople	July 10–16		5
YELLOW FEVER			
Ecuador: Guayaquil	July 1–15	1	1
Milagro	July 1–15	7	5
Naranjito	July 1–15	2	
Taguachi	July 1–15		1
Mexico: Merida	Aug. 8	2	
In the lazaretto.			
Venezuela: Caracas	July 1–21	3	1
Maiquetia	July 22	2	
PLAGUE			
Brazil: Para	Aug. 3–4	1	1
Chile: Iquique	June 11–July 1	5	2
China: Amoy	July 11–17		2
Hongkong	June 19–24	25	8
Ecuador: Guayaquil	July 1–15	7	1
India: Calcutta	June 4–17		87
Kurrachi	June 25–July 1	6	4
Rangoon	May 1–31	278	267
Indo-China: Saigon	June 12–25	59	17
Japan: Formosa	June 25–July 1	4	5
In the southern part.			
Straits Settlements: Singapore	June 11–17	1	1
Venezuela: Caracas	July 1–6	1	
SMALLPOX			
Argentina: Buenos Aires	May 1–31		34
Rosario	Apr. 1–May 31		75
Canada: Montreal	July 23–29	1	
Ottawa	July 23–29	3	
Vancouver	July 9–15	1	
Winnipeg	July 23–29	1	
Brazil: Para	Aug. 3		Present
Pernambuco	June 1–15		86
Chile: Talcuhuana	June 25–July 1	3	
Valparaiso	June 25–July 1	59	
Deaths seldom reported.			
China: Hongkong	June 19–24	3	2
Egypt: Port Said	June 18–July 1	3	4
France: Havre	July 16–22	1	1
Paris	July 9–15	2	
Germany			
Total July 16–22: cases, 2.			
Bremen	July 9–15	1	
Great Britain: Birmingham	July 9–15		1
Dundee	July 18–22	4	
India: Madras	July 12–18	8	4

THE TRIUMPH OF AMERICAN MEDICINE IN THE CONSTRUCTION OF THE PANAMA CANAL.

BY J. EWING MEARS, M.D.,

PHILADELPHIA.

IN a paper published in the volume of Transactions of the American Surgical Association for 1908, entitled "Modern Medicine and Surgery in the Orient," I discussed the subject of the conservation of the public health, and directed attention to the methods of sanitation practised in the countries of the Orient, as I had observed them in a visit which I had recently made to these countries. In concluding the paper, I spoke of what had been accomplished in our country, and referred to the great work done in the Isthmian Canal Zone by Col. W. C. Gorgas, U. S. A., Chief Sanitary Officer, Isthmian Canal Zone, and stated that his achievements had made the construction of the Canal possible, claiming that its completion would be a triumph of American Medicine.

During the past winter I have visited the Canal Zone and have had, through the courtesy of Col. Gorgas, an opportunity to observe the marvelous results obtained in the conservation of the health, by the methods of sanitation employed, of the large army of officials and work people, some 47,000 in number, engaged in the stupendous undertaking of the Canal construction.

In order to appreciate fully what has been accomplished by the system of sanitation inaugurated by Col. Gorgas and so perfectly conducted by him and his able corps of assistants, it is necessary to consider the conditions of health which, up to the beginning of the work by the Americans, prevailed in the cities of Colon and Panama, and in what is now known as the Canal Zone, ten miles of territory acquired by purchase by the United States Government from the Republic of Panama, and which is located five miles on either side of the Canal route, including an area of three hundred and twenty-two square miles.

For nearly four hundred years that portion of the neck of land between the Continents of North and South America, now called the Isthmus of Panama, has been known to be one of the unhealthiest regions of the Globe. Uninhabitable to any but the few natives who made their homes there, and the residents of the cities of Panama and Chagres, at the mouth of the Chagres River, on the Atlantic Ocean, with their blood charged to the full with malarial parasites, who fell in great numbers victims to the deadly scourges of malarial and yellow fever, known in their most pernicious forms as Chagres fever, which, existing as endemic forms, frequently assumed the proportions of devastating epidemics, developing under the climatic conditions which encouraged the facile breeding of the anopheles mosquitoes, and the absence of any quarantine regulations which controlled the influx of the stegomyia species, or of its work in transmitting infection.

The eager quest of gold in the waters and lands of California brought many white people to the Isthmus in the year 1849 who desired in this way to avoid the longer and much delayed route around Cape Horn. On foot, on mule, and in vehicles of varied design they fought their way through the almost impenetrable jungle, in torrid heat, under blistering sun-rays, and in torrential rains. Overcome by climatic conditions and exhausted by fatigue, they fell easy victims to the fierce onslaught of the native anopheles, which in swarming myriads welcomed the invasion of new blood. Many laid down to die to find an uninviting grave in the desolate morass and in the tangled jungle

The tide of travel across the Isthmus increased to such extent as to encourage the building of a railroad from the Atlantic to the Pacific Ocean. This was undertaken in 1849 and completed in 1855, under very great difficulties in railway construction, owing to the conditions of land and soil. Here again the anopheles and stegomyia played havoc in the ranks of the laborers, and so many perished from disease that it became a common saying that every railroad tie represented the dead body of a workman.

Ignorant of the cause of malarial and yellow fevers and their methods of transmission, the medical officers in charge were forced to content themselves simply in combating the developed disease with antimalarial remedies and those commonly employed in treating yellow fever.

In the year 1881 another invasion of the Isthmus took place, when the original French company began the construction of an Isthmian Canal. Eleven years—1881 to 1892—were consumed in construction work before the effort was abandoned, with very little accomplished comparatively in the way of a completed canal. While it is stated that corrupt methods and graft played an important part in producing the failure, it is believed that diseases, now preventable, were chiefly responsible. The fifty buildings devoted to hospital purposes left by the French bear testimony to the fact that the medical department was fully organized, but its work was largely ineffective, because the state of knowledge then existing was defective in producing information as to the prevention of the diseases the medical officers were called upon to combat.

That heroic son of Medicine, Dr. Lazear, U. S. A., had not given his life to demonstrate that the infection of yellow fever was transmitted by the mosquito, Stegomyia fasciata, and Col. Gorgas, U. S. A., had not driven disease and pestilence out of Havana by the enlightened methods of sanitation

devised by him. The hopeless contest waged against disease by the French is illustrated in the statement made by Lieut. Constant Cordier, U. S. A., in the thesis presented by him to the San Marcos University, Lima, Peru, for the degree of Doctor of Philosophy, to the effect that in five years the French lost eleven-sixteenths of the working force, one-third of the number French subjects. Out of the twenty-four Sisters of Charity engaged in nursing in the Ancon Hospital, twenty died of yellow fever. Of seventeen engineers who came on one steamer, sixteen died. During the period of time in which the Panama Railroad was undergoing construction, and in the eleven years in which the French were engaged in their efforts to construct the Canal the losses by death from malarial and yellow fever were as great as any suffered by the white race in the history of the tropics.

In the year 1904, when the United States Government took charge of the Canal Zone and began the Canal construction, Col. Gorgas, fresh from the victories won by him in Cuba, was assigned to duty as the Chief Sanitary Officer in the Zone, and began the colossal work of transforming a territorial area of three hundred and twenty-two square miles, surcharged with disease-producing causes, into a region so free from disease that the mortality among the officials and working people is now not greater than that of the towns and cities of our country.

This standard of health was regarded as essential, in order (1) to attract and to protect skilled white workmen who came from their homes in our country, and (2) to maintain a condition of health among all classes of the working force, which would contribute to the continuous and successful labor which was necessary in accomplishing the Canal construction. Col. Gorgas was not only charged with the duty of converting the intricate recesses of the jungle into healthful homes for the employees, but also he was confronted with the difficult task of renovating two cities, aggregating in population fifty thousand people, one of which had been for quite two and a half centuries the birthplace and the home of pestilence and disease. Such were the conditions which existed within the Canal Zone which demanded treatment. At either end of the Zone were gates which, unless securely closed against the introduction of infective diseases, would prove to be fertile sources of conditions which would render futile the efforts made to establish correct sanitary methods within the Zone. These were the harbors of Colon, on the Atlantic Ocean, and Panama, on the Pacific Ocean.

Into these harbors came the trade of the world, in vessels from the Eastern and Western Hemispheres. On the Atlantic side the islands of the Antilles and the many ports of the eastern coast of Central and South America had free intercourse with the Zone through the Colon harbor. In many of the ports yellow fever existed in endemic form. History records that for over one hundred and fifty years yellow fever had existed in Havana, Cuba, as an endemic disease. On the west coast of South America similar conditions existed, many ports not only giving residence to the infective fevers but also to the plague.

In Guayaquil, Ecuador, it is stated that the inhabitants are inclined to rejoice in the presence of yellow fever, as this condition of health keeps out the foreigners who would invade the country and rob them of their business opportunities.

In many of the Pacific seaports the plague has a footing, and during my visit to some of them deaths occurred from it; the same may be said of the Atlantic ports. It is thus to be seen that not only was the Zone area to be purified and purged of disease causes, but it was to be protected from the invasion of disease through the gates of commerce at each end. These conditions, within and without confronted Col. Gorgas in the organization of his sanitary system, and enhanced greatly the difficulties to be overcome in perfecting it. Two chief propositions present themselves in the study of the sanitary system which was planned and adopted. The first one may be regarded as of major importance—that of the prevention of disease by the removal of causes—and the second, the guardianship of the well and the care of the sick from all causes and of those sustaining injuries in the work of canal construction.

The general state of health in the community of officials and work people is maintained by rigid inspection of all food issued for consumption and by weekly examinations and analyses of the water supply from all sources, municipal water supplies, streams, and springs, and condensed water. The houses in which officials and workpeople live claim special attention, and equally well those of the inhabitants of Colon and Panama City. While the political government of these cities, which are within the limits of the Canal Zone, rests with the governmental authorities of the Republic, the sanitary and police control are supervised by the officers of the Canal Commission under the authority of the United States Government. This is absolutely necessary for the maintenance of public order and of correct sanitary conditions within the Zone. The plans for the construction of new houses in these cities must be submitted for approval to the health officers, and the buildings within the Zone for the employees are constructed under the same exacting conditions. Owing to the presence of the plague on both coasts of Central and South America, it is especially necessary that new houses should be constructed so as to make them rat-proof and prevent the harboring of rats. These conditions are accomplished by either raising them three feet from the ground on supports of concrete or other material, covered with tin, so that the rats cannot secure a footing on them, or if placed on the ground they must rest on a floor of concrete All buildings are submitted to inspection at regular intervals; those not in a sanitary condition in the cities must be placed in that condition, if possible, by the owner, or they are condemned and destroyed. Disinfection and fumigation are practised in all buildings in which cases of infectious diseases have occurred. Permits to repair buildings and to occupy them temporarily or permanently must be obtained from the health officials.

In the cities of Panama and Colon systems of sewerage have been installed, and all buildings must make connections with the sewers. This condition exists in all of the communities in which residential or hospital buildings are located. Outside of the sewered areas in the native villages pit closets are used, and are disinfected weekly with a solution of larvacide, a very effective and cheap preparation, consisting of crude carbolic acid and caustic soda.

Uncompromising warfare is carried on against the mosquito, anopheles, and stegomyia. In the cities and in the regions of the Zone occupied by officers or laborers all breeding places are either destroyed or kept in a sanitary condition, free from

larvæ, by oiling or the use of larvacide. Stagnant pools and collections of water are filled up or in large areas drained by ditches which are maintained in sanitary condition. Special attention is given to defective roof gutters, which become prolific breeding places in the water which remains in them owing to the want of proper inclination to carry off all water which comes into them in a rainfall. When very defective by reason of sagging, they are removed, and the owners of buildings are required to replace those thus disposed of by new gutters. In some instances simple punching of the sagging portion keeps the gutter empty.

At first considerable opposition was met with, and the Governor of the District was requested to amend the decree giving authority to the health officials, so that this important work could not be interfered with. All receptacles containing water for use are required to be screened. The constant inspection of known breeding places is maintained, and the mosquito brigade is on continuous and vigilant duty. Persistent search is made for suspected places, and the surveillance is never relaxed. Although no case of yellow fever has occurred on the Canal Zone since the year 1905, the search for the stegomyia and its destruction continues.

The fact that both the adult and larvæ of stegomyia species are transported by railroad trains exposes the Zone to dangers which require that the most exacting precautions should be taken; their escape from patients before entering quarantine is quite within the range of possibility and greatly increases the work of prevention. Fortunately their recognition is within scientific knowledge, and their detection is thus facilitated. All patients are transported to the hospitals on screened stretchers or in screened ambulances.

Notwithstanding the rigid system of prevention, through sanitary measures which have been established on the Zone, the community is still further protected from the invasion of the mosquito the breeding places of which may happen to escape destruction by a most perfect plan of house screening. Residences particularly are screened, the rustless wire (copper) being employed for this purpose. Not only are the doors and windows protected, but the porches, including first and second story, are securely enclosed. On first view, the appearance is novel, and quite suggestive of huge bird cages. The assured safety thus given dissipates any feeling that the inmates are unwilling occupants of the apparent houses of detention.

The known part taken by the fly, the common house fly, in transporting germs of diseases makes it a source of grave danger, and provokes measures of protection against its existence. These measures consist in supplying all buildings of the Commission with range closets, water and sewer connections. The pit closets in the native villages are, so far as possible, made fly-proof, and are disinfected weekly by a solution of larvacide to prevent fly-breeding. By this means of prevention the fly becomes a *rara avis* within the Zone limits, and is very much less in number than in the villages and towns of our country. During my stay I saw but one specimen, and the comfort enjoyed in the homes by their absence is very great, and quite in contrast to the discomfort caused by them in our homes, be it in the country or in the town.

The rat as the habitat in its hairy integument of the plague flea demands extermination. The annual report of the Department of Sanitation of the Isthmian Canal Commission for 1909 gives the number of rats caught and killed in Panama City during the year as 17,004; in the city of Colon the number killed was 7,284. In Panama City 673 dogs were poisoned, and in Colon 66. The report of the Board of Health Laboratory, included in the report of the Department of Sanitation, contains record of 24 examinations of rabies and suspects, and 11 cases of preventive treatment for hydrophobia were completed.

An interesting item relates to the existence of crab holes along the shores. In Colon 7,000 were oiled and 224,220 were worked. In Cristobel 43,200 were worked, and in Mount Hope 73,229. Grass and weeds afford a harbor for mosquitos. In Panama City 1,961,395 square feet of weeds and grass were cut and removed. In Bocas del Toro 340 square yards were cut and burned. In Colon 460 acres of vegetation were removed. In Colon 1,319,514 water receptacles were treated, and in Bocas del Toro 554 were overturned—158 breeding places of the mosquito were found in barrels, tubs, etc., and destroyed.

The antimalarial crusade is carried into the houses and into the public eating places of the employees of the Canal Commission. On the tables are placed bottles of the tonic quinine solution which is taken with the meals. Blood examinations are made to determine the presence of the malarial parasite. The complete report of Col. Gorgas for the year 1909 states the issues of quinine for the year to have been 3,148,053 pounds avordupois, an average per month of 262,337 pounds, representing an issue of 66.74 pounds during the year for each of the 47,167 employees reported as being present and engaged in the Canal construction.

I have selected these few items from Col. Gorgas' report to illustrate, in brief, the character and magnitude of the work carried on to prevent sickness among the employees of the Isthmian Canal Commission, and to maintain a state of health conducive to the most successful results in conducting the constructive work on the Canal. As a test of the success of the sanitary work it is interesting to consider, among other diseases, the hospital admissions and deaths from malaria in the years 1905 to 1909.

Hospital admissions per thousand of employees: 1905, 514; 1906, 821; 1908, 282; 1909, 215. In 1906, owing to exceptional rains, mosquitos were bred in many places and in large numbers, and it seemed not quite possible to control their existence by the measures which, under ordinary conditions, proved to be so successful. In the same period of time the deaths from malaria were: 1905, 86; 1906, 233; 1908, 73; 1909, 52. The vital statistics for 1909, as given by Col. Gorgas in his report, showed a marked improvement. In 1905 and 1906, with the number of employees 10,512 and 26,547, respectively, the death rate was 25.86 and 41.73. In 1908 and 1909, with the number of employees 43,891 and 47,167, respectively, the death rate was 13.01 and 10.64. In the year 1909 the annual death rate per thousand of 11,662 white employees was 6.43 from disease and 3.43 from violence; total, 9.86. Of Americans, average number 8,386, including employees and their families, the death rate per thousand was: from disease, 4.05; from violence, 2.27; total, 6.32. A further statement of the death rate of the total population, including the cities of Colon and Panama and the country between them, shows

it to have been, in 1905, 49.94 and, in 1909, 18.19.

Assuredly nothing can be added to these clear and authentic statements to demonstrate the value of the system of sanitary work inaugurated by Col. Gorgas and so faithfully and successfully conducted by him and his corps of able assistants.

From the consideration of the measures taken to prevent disease it will be interesting to observe how the sick are cared for. For the entire sanitary work on the Zone and in the cities of Panama and Colon there is a personnel of 1,244, the average number of employees at work during the year, distributed in the chief sanitary office, care of property, quarantine service, health officers, in hospitals, sanatorium, asylum for lepers, and dispensaries. There are four hospitals, including a leper asylum, and one sanatorium and nineteen dispensaries. There is a hospital for the insane, which is conducted for the Republic of Panama, which pays to the Commission for each patient 75 cents per day. The Canal Zone Government pays 30 cents a day, and outside patients, as members of the families of employees and others, pay 30 cents a day in the General Hospital. Altogether the paying patients from all sources in the Zone contribute in the year $98,081.72.

Ancon is the Zone town at the Panama end of the Canal and opposite to Panama City. Here is the office of the Chief Sanitary Officer and the Ancon Hospital, which is the largest. This was the site of the French Hospitals. Of the seventy-five buildings for hospital purposes, about fifty were built by the French, which were found by the Americans covered by the jungle. Twenty-five of the buildings are occupied by the staff. In the Ancon Hospital there are 900 beds for medical purposes, in 27 wards; 320 beds for surgical patients, in 10 wards; 5 wards for contagious and infectious diseases; 2 wards and 6 rooms for tuberculosis.

A maternity department is conducted for the families of white American employees, who pay in private rooms $2.50 a day and $1 in the general wards. Thirty contract physicians are employed by the Isthmian Commission, who report to Col. Gorgas, Chief Medical Officer. One hundred and two trained nurses, 93 female, 9 male, trained in the United States, are on duty, with 138 attendants acting as orderlies. The Colon, Culebra, and Santo Tomas Hospitals, with the leper asylum at Palo Seco and the Tobago Sanatorium, have much less capacity and require the services of a much smaller corps of officers and attendants. Attached to the daily trains on the Panama Railroad from Colon to Panama are hospital cars, arranged with berths which can be raised and lowered conveniently, forming comfortable stretchers and beds for the sick and injured who may be taken aboard at the different stations, and in this manner transported with a minimum degree of discomfort to the Ancon Hospital. In charge of these cars is a medical officer, with attendants, who gives attention to patients *en route*, and such medical services as may be needed. Four chaplains are assigned to duty in the hospitals, and two chapels, one Protestant and one Roman Catholic, supply places of worship. Four buildings, at different points in the Zone, provided by the Isthmian Commission, are devoted to the work of the Young Men's Christian Association, containing reading, library, and amusement rooms.

The milk supply comes from the dairy, in which there are 93 cows, which were brought from the United States and were carefully tested for tuberculosis before being sent and after arrival on the Zone. Great care is given to the feeding, stabling, and milking of the cows, and prompt measures taken in the treatment of any diseases which may occur. The milk is pasteurized. The poultry farm contains some 600 chickens, which are carefully watched for diseases. All dying from disease are autopsied and the cause of death determined and recorded.

One of the most important sections of the Isthmian Canal Commission is the laboratory of the Board of Health, forming a part of the department of sanitation, in charge of Samuel T. Darling, M. D., chief of the laboratory. Through the courtesy of Dr. Darling I was permitted to observe the methods of work carried on in the laboratory, which made my visit full of interest. The equipment of the laboratory is complete, the Government, through the Canal Commission, providing all that is necessary to conduct the important work of this department. The routine work in the laboratory includes examinations, pathological and bacteriological, for the hospitals, autopsies, surgical pathology studies, Wassermann reactions, blood cultures, vaccines, chemical analyses for the Commission and chemical examinations for the Ancon and other hospitals of milk and foods (toxicological), special examinations of urine, etc., chemical, bacteriological, and microscopic examination of all Zone water supplies, including five reservoirs. The research work involves various subjects, reports upon which have been published by Dr. Darling. Possibly the most important is that entitled "Studies in Relation to Malaria," published by the Government Printing Office, Washington, D. C., 1910. Most elaborate experiments were conducted in determining some of the factors concerned in the prevention and transmission of malarial fever in the Canal Zone. Among the most interesting results obtained was the determination of the influence exerted by quinine upon the malarial parasite.

The recognition of the mosquitoes common to the Zone, their breeding habits, and the determination made of the species of anopheles hospitable to malaria and those transmitting it claimed critical attention and study. Eleven species of anopheles were collected in the Canal Zone in the five years given to the study. It is interesting to note that observation determined the fact that the characteristic musical note of the mosquito is caused by the vibration of the proboscis and not the wings, as commonly believed. The proboscis is, therefore, not only a weapon of offence, but an organ of harmony—an inharmonious combination.

In concluding this necessarily brief and incomplete recital of what sanitary science in this day has accomplished in the conservation of the health of the working community in the Canal Zone, many questions of far-reaching importance suggest themselves for consideration and for study. To one, as is the writer, familiar by actual contact in field and hospital with the appalling conditions which, through the absence of scientific knowledge, confronted the medical officer of the army in the days of the Civil War, great must be his satisfaction in noting the changes which the last half century has wrought in the development and progress of scientific medicine.

In truth and in justice it can be said that in no

department of medical effort has progress been more pronounced than in the medical corps of our public service, army, navy, and marine-hospital service. The writer feels in this respect that he may be permitted to speak with a shadow of authority, as it came to him in his earlier teaching days to place in the medical department of the public service about ninety of his private students. He knew of the conditions existing in those days and of the requirements exacted by the boards of examination guarding the gates of admission into the service, and with inspiring appreciation and gratifying pride he has watched the gradual but sure advancement in scientific knowledge and in adaptive methods which has taken place.

The war colleges of our army, the hospital ships of our navy, the research laboratories of our marine-hospital service all speak in resounding tones of progress in scientific medicine, and place our public service in the very forefront of achievement among the nations of the world. No longer does the medical department of the different branches of the military and public service occupy the subordinate position assigned to it in the days of the Napoleonic campaigns, or even in those of more recent times.

In the earlier days the commanding general of the army concerned himself much, through his under-officers, about the state of efficiency of his commissary and quatermasters' departments, in order that he might without interruption continue his line of march to meet the enemy and engage him in battle. The medical department was, in a certain sense, an after-thought: the sick and wounded could be left behind in field hospital or in barracks, but the impedimenta, the quartermaster and commissary stores must be in as efficient a state as possible. He did not know and his medical officers could not tell him at that time how important, absolutely necessary, it was that the medical officer should march side by side, as it were, with the soldier.

Under his care the soldier endures the fatigue of the march and comes to the battle line as an efficient agent in the conflict; between him and disease and pestilence the medical officer stands, without fear and with undaunted courage, erecting barriers of defence and battling, it may be with greater skill than the officer of the line, against the onslaught of the ofttimes concealed enemy. In his hands the soldier becomes a unit of protection against all of the influences of his environment and the methods of his life—he is not only taught to protect himself, but to protect all about him. In a sense every act of his life, as every function of his physical being, becomes the intelligent care of the medical officer. Such, in truth, are the conditions in existence to day under the progressive methods which the advanced state of medical science confers.

It may be urged that it requires military discipline to achieve such results as we observe in the Canal Zone. Recognizing, as we all must, the influence exerted by a state of military control in conquering unsanitary conditions and in obtaining unresisting compliance with those which are conducive, in all respects, to the conservation of health which may be permanently maintained, we find some examples of places presenting conditions similar to those which had existed in the Canal Zone, and which have been completely removed by civic efforts.

In a visit made in the last winter to South America, I landed in Santos, Brazil, city of 41,000 population, and one of the best ports on the Atlantic Ocean. A few years ago this port was devastated by raging epidemics of yellow fever. To such an extent did the disease prevail that vessels coming into the port lost in several instances, and very quickly, their entire crews from the disease, officers and men, before they could be unloaded. I was told of one instance in which a vessel lay anchored in the harbor for a period of eighteen months unloaded, with cargo perishing in the hold.

Inspired by the fact that this city was the greatest shipping port of coffee in the world, the government and municipal authorities inaugurated a system of modern hygienic improvements which destroyed the breeding places of the stegomyia mosquito, and banished yellow fever, converting its beautiful harbor from a home of pestilence into an attractive seaside home, with the ships of many nations unloading and loading in guaranteed security alongside of its commodious and well-arranged quays.

Such results had been obtained by civic effort, and they may be accomplished in other places where knowledge of sanitary science, combined with intelligent cooperation—freed from the demoralizing and destroying grasp of the political boss, surcharged with graft—is employed in correcting unsanitary conditions, conducing, in this manner, to the prevention and to the staying of the ravages of disease.

The world should not, as we hope and believe it will not, look again upon a picture such as the Chickamauga Camp in the Spanish-American War, which portrayed in such lurid colors the humiliation of American medicine. While it is true we were on the eve of discoveries of great import, born of the experience which we gained in the occurrence and in the progress of the war, it may be said, without fear of successful contradiction, that the conditions which provoked such holocausts were in large measure preventable. It is true that we did not know of vaccination as a prophylactic measure against typhoid fever—a recent gift of laboratory research and of experimental medicine, which will take its place with vaccination against smallpox as a monumental contribution to the promotion of the well-being and welfare of the human race—we did know, however, of the great necessity of microscopic, chemical, and bacteriological examinations of food and drink supplies. The bacillus of typhoid fever had been isolated in the year 1880, and we knew the importance of its destruction in the excreta. We knew of the necessity of maintaining all sinks and pits in rigid sanitary conditions, destroying by the free application of the most powerful disinfectants all microorganisms. Our knowledge, at the time, of the part taken by the common house fly in conveying disease germs was sufficient to provoke measures of protection against it, and the employment of agents to prevent fly breeding in all places favorable to such conditions. We had sat for two decades or more under the instruction of the great teacher who had taught us the far-reaching principles of antisepsis, and had demonstrated its practical application in all conditions involving the sick and wounded—the subjects of the wounds of accident and of the wounds of intention. We knew the value of incineration in the disposal of all refuse matter. The gospel of cleanliness, evolving asepsis, as the physician and the surgeon understand it, or should

understand it, had been preached abroad in the land, enjoining all to be clean, through its unremitting application in practice.

All of these things and many more we did know, and yet the dread disease typhoid fever stalked through the camp, apparently unrestrained, laying low one-sixth of the entire command—20,000 cases out of an army corps of 120,000 troops—with a case mortality of 0.7 per cent. The annals of civilized warfare do not present a page quite so black, recording conditions which the knowledge of the day should not have permitted to exist.

The progress of scientific medicine is onward, and to-day in the camps of our armies, on the battleships of our navy, and at the quarantine stations of our marine-hospital service it shines with added luster, the medical officer taking his place, as of right it belongs to him, in the front rank with those whose efforts contribute to civil and military efficiency. Moved with pride by the achievements of his noble profession and inspired by loyal devotion to the corps of which he is a member, he bears aloft the banner of progress and scientific research unfurled by that distinguished disciple of medicine and honored medical officer of the United States Army, William Beaumont, who nearly a century ago gave to the world and to scientific medicine, obtained through accurate research work in the living subject, the first knowledge it had of the functions of the stomach and of the constituent elements of the gastric juice and their action on foods. His name will live as the pioneer in scientific research in the history of American medicine.

Truly, may we not congratulate our professional brethren who have so unselfishly devoted their talents and their lives to the service of their country upon the great work they have accomplished, which stirs our national pride, and proclaims to the world their monumental achievements, as the President and their Commander-in-Chief has so well proclaimed them, "Marvels of American courage, energy, and scientific thoroughness, skill, research, and original discovery." So long as preventable destroying diseases flee before the conquering hosts of efficient sanitation, so long will the labors of these noble benefactors of the human race be cherished. Upon their brows we place wreaths of victory, laurels won not in the fierce conflict of clashing arms, but in the home and in the daily walk in life, over which the Angel of Peace spreads her golden wings. As we acclaim them victors in peace, no less than in war, we enshrine them in the grateful hearts of their countrymen.

FRACTURES OF THE FEMUR.

By J. ALLEN GILBERT, Ph.D., M.D.,

PORTLAND, ORE.

The following method of treating fractures of the femur located anywhere above the lower third has proven so satisfactory that presentation to the profession seems advisable. Some of the principles and parts of the apparatus will be recognized as old friends, but the general scheme of the method for facilitating the application of extension and the method of applying the casts and its accessories used to that end may possibly be of help in this trying class of cases. Results, so far as shortening, danger of pneumonia, and pain during the period in bed are concerned, recommend the present method in preference to the pulley and weight. Experience with eight cases in which the following method was used was so thoroughly satisfactory that description of the apparatus and method of applying the same are given below.

Apparatus—(Key to the letters used in the cuts): A—Pulley with screw-eye and long rope. B—Inch strips of fly-screen netting long enough to reach

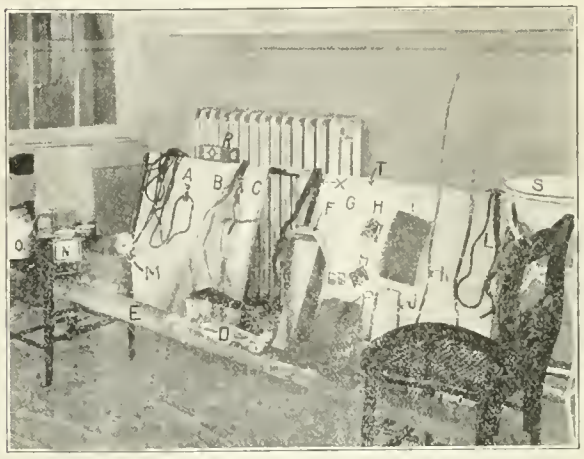

Fig. 1.

around the body. C—Tin scissors to cut fly-screen and to remove the cast after union of the bone. D—Large 12-inch strap-hinge, with one strap bent at about 4 inches from the joint, screwed to a board with an upright support at its end for the unfastened end of the hinge. E—A 2 by 4-inch piece about 6 feet long (strong board just as good). F—Board about 3 by 4 inches, with a wire handle to which is fastened a yard of heavy rubber elastic X. To this is attached the usual adhesive of a Buck's extension. G—Two large buckles with about 18 inches of tape fastened to them to be incorporated in the plaster cast U. H—Two folded pads of fly-screen, to be slipped over the ends of K to prevent it being pushed up through the cast U by the pressure upward from the rubber elastic X. I—Piece of fly-screen netting to be incorporated in the cast U, just over the head of the femur, which is the weakest part of the cast. J—Iron support to be hooked on to K even with the foot. This serves as a support to keep the foot from everting and also supports the bed clothes. K—Strap-iron band to extend from just above the crest of the ilium down

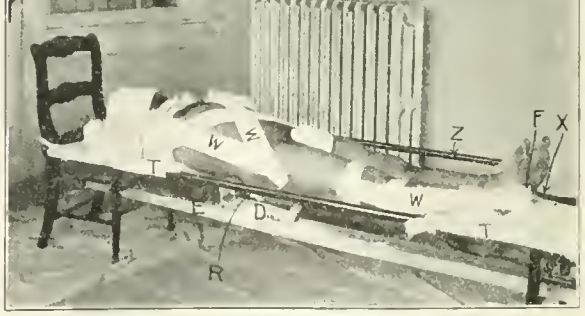

Fig. 2.

along the outer surface of the leg to about 9 inches below the foot, across at right angles, over to the inner aspect of the foot, and up again at right angles following the inner surface of the limb to about two-thirds of the way between the knee and perineum. Below the foot it must be as wide as the

length of F, which must be able to slide freely between the arms of the iron. The strap-iron should be of a strength to allow bending it to fit the curves of the leg. Strap-iron ¾ or ⅝ by ⅛ inches will be found convenient. L—Rope about 6 feet long. M—Spool of 3-inch by 10 yards. Z O—Adhesive

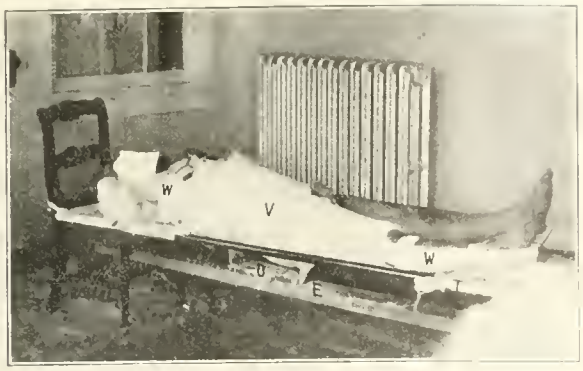

Fig. 3.

plaster. N—Box of plaster bandages, 3 or 3½ inches wide. O—Extra plaster of paris to make into a mush and work into the meshes of the fly-screen used. P—Two or three 1-inch boards 4 by 8 inches, with which to block up the hinge D and bring it to about the same height as the seats of the chairs. R—4-ounce package of cotton. S—Basin of water deep enough to submerge a plaster bandage standing on end. T—Gas pipe frame (Bradford), 6 feet by 2½ feet, over each end of which are pulled tightly fitting canvas slips, leaving space for a bed pan in the middle. The canvas slip under the shoulder can advantageously be slightly longer than the one under the feet. U—Plaster of paris cast. V—Thin layer of cotton over the body where the cast is to be applied. W—Adhesive strips 3 inches wide. X—Rubber elastic band. Y—A pad to relieve pressure on the heel. Z—The frame made of 1-inch gas pipe, 6 feet long and 2½ feet wide. The apparatus, including plaster and all, can be prepared at a cost of about $5.

Steps in Putting on the Cast.—1. Give hypo-

Fig. 4

dermic of ⅛ to ½ grain morphine, according to size of the patient.

2. While patient is still in bed place adhesive strips W, as shown in Fig. 2. Warm them so they will adhere well. On the side of the break the body strips should only extend from the head of the femur to the shoulder. On the uninjured side the lateral strip may extend from the knee to the shoulder. Diagonals across the abdomen are also placed to increase the adhesive surface. On the lower limb are placed the ordinary adhesive strips for a Buck's extension. Instead of the pulley and weights

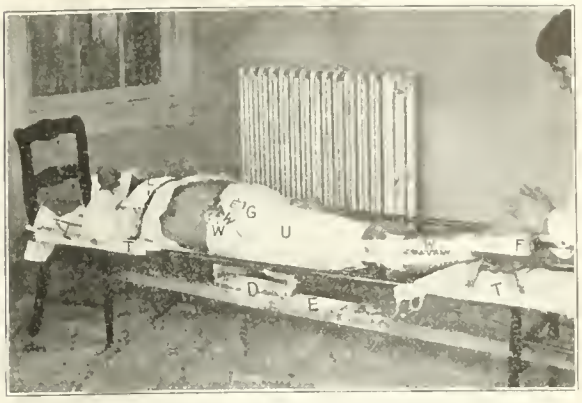

Fig. 5.

the extension is to be obtained by the rubber elastic band X.

3. Put side of the frame T under the sheet and up against the patient as he lies on the bed.

4. Pull him up on the frame by pulling the sheet without lifting him.

5. Place a 2 by 4 on rungs of two chairs, facing each other. Set the mounted hinge D on this and block it up with boards P till it is level with the seats of the chairs, Figs. 1 and 2. If the springs of the bed on which he is to lie are weak let the hinge be a little lower than the chair seats to allow for sagging of the bed. It would be even better to make a fracture bed by placing boards between the springs and the mattress.

6. While two assistants lift the frame at the ends, adjust the hinge, well covered with cotton, so that the small end of the hinge comes to the top of the coccyx or a little below.

7. Gradually lower the patient's shoulders and feet till the frame rests upon the two chairs, Fig 2.

8. Slide the slips up and down in the gas pipe

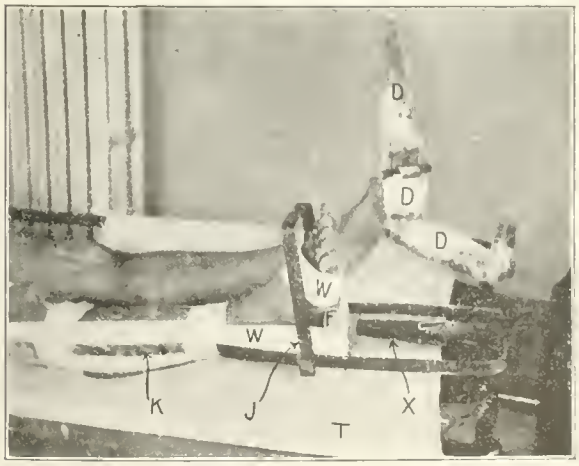

Fig. 6.

frame till they are out of the field of operation in placing the cast, and cover the body and broken thigh from the ribs to the knee with a thin layer of cotton, Fig. 3.—If preferred the body may be vaselined in place of the cotton.

9. With the rope L fasten the patient to the

chair at his head by passing the rope over the chest, under both arms and around the back of the chair, where it can be tied, Figs. 4 and 5.

10. Let an assistant make steady and continuous traction on the foot holding the previously everted foot in an upright position, Figs. 4 and 5.

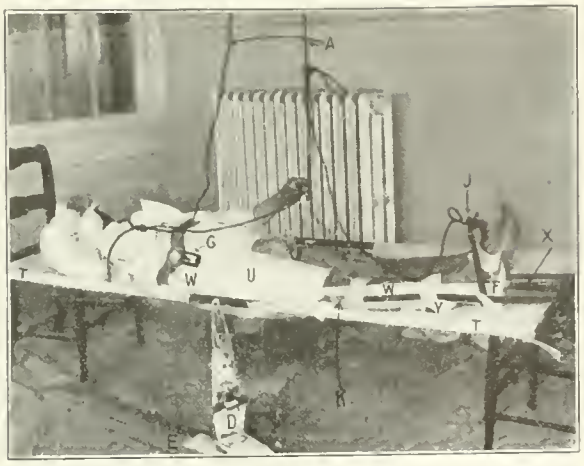

Fig. 7.

11. Enclose the part of the body covered by cotton in a cast U of sufficient strength to protect the body from the apparatus to be incorporated later. Enclose the free strap of the hinge under the cast, but be sure not to have any laps of the plaster bandage above the joint of the hinge so that it can be slipped out later. It is well also to apply a liberal pad of cotton in the groin before applying the cast. This can be removed later, leaving the genitals free and easy of access for cleansing purposes.

12. Adjust the strap-iron band K to the curves of the cast and leg. Slip the fly-screen pads H over each end of the band, one just above the ilium and the other on the inner aspect of the thigh, about two-thirds of the way from the knee to the perineum. Insert the fly-screen sheet I under the band over the hip and bind it all in place with a number of the inch strips of fly-screen B, passing the strips around the outer and inner arms of the iron band, as in Fig. 4. Keep up steady traction on the foot. The rope under the arms gives counter traction.

13. Work a mush of plaster of Paris into the meshes of the fly-screen.

14. Over this apply a heavy cast U, covering all from the ribs to the knee, leaving the uninjured thigh free, of course, Fig. 5. Reinforce the cast at the hip with extra laps of plaster bandage. Here is the weakest point in the cast.

15. While putting on this outer cast incorporate the tapes holding the large buckles G, carrying the tape back and forth, interweaving it among the separate layers of the cast, bringing the buckles finally four or five inches from the top of the cast.

16. Turn down the ends of the adhesive strips above the cast, fold them into straps, and pass them through the buckles G, each buckle thus receiving one diagonal and one lateral strip. The height of the cast can be regulated later, if desired, by these straps, Figs. 5 and 7.

17. Untie the rope holding the patient to the chair at his head and apply the extension below by carrying the rubber elastic X around the end of the strap-iron band and through the handle to block F, as often and as tightly as is required to hold the lower ends of the two femurs even, Fig. 6.

18. Hook the iron support J to the iron band just over the toes and fasten the foot to the inner arm of this support with an adhesive strip to prevent eversion of the foot, Fig. 6. After adjusting this iron support to its proper place, it can be fastened to the strap-iron band by a little adhesive strip, Fig. 7. The iron support J also supports the weight of the bed clothes.

19. By lifting the frame raise the patient. This allows the base of the hinge to drop down and swing from the strap of the hinge still held between the cast and the body. Slip this upward and take it out. The patient can then be put to bed *on the frame*. Fig. 8 shows a patient on a stretcher with the frame still under him. Sheets 1 and 2 can be slipped apart, leaving a space between them, where 3 can do duty immediately under the rectum, where the bed pan is to be used. Sheet 3 is under the frame so that it remains on the bed when the frame and sheets 1 and 2 are raised to insert the bed pan. The pad Y will usually be found advisable to relieve pressure on the heel. A pillow under the leg will serve this purpose well.

20. Remove the bedstead from the room. Place the four corners of the bed-springs and mattress on four boxes or four chairs in the middle of the room. This allows you to get on all sides of the patient without obstruction. The pulley A, in Fig. 1, should be screwed into a joist in the ceiling, just over the center of the bed.

21. Pass the long rope A, Figs. 7 and 8, under the arm on the injured side, behind the back, over the shoulder of the uninjured side up through a pulley screwed into the ceiling over the center of the bed and tie it to the supporting rod at the toe. Connect the two ropes going to the pulley so that the patient can draw either one to him. By pulling down on the rope around his shoulders he can raise his leg enough for the nurse to make the lower half of the bed. By pulling down on the rope fastened to this support over his toes he can raise his shoulders for adjustment of pillows or making the upper half of the bed. The bed can best be dressed by using two sheets between the frame and the body, one to reach from the head of the bed to the buttocks, the other from the foot of the bed to a little below the buttocks, the intervening space being sufficient to allow the use of a bed pan under the sheets and frame. By raising the frame and patient at the foot, supporting the frame with a box of right

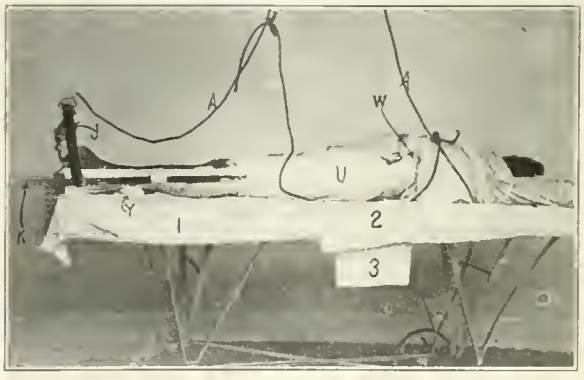

Fig. 8.

height, the bed pan can be slipped under and removed without disturbing either the patient or the extension. By using the uninjured limb and pulling on the ropes with his hands, the patient is able to move and turn himself at will. There is comparatively little pain during the applying of the cast

and during the period in bed. The patient stays on the frame till removal of the cast, which should be done from five weeks up, according to the age and general condition of the patient.

Advantages of the Method.—(1) Extension is continuous, regardless of the position of the patient.

(2) Elevation of the foot of the bed unnecessary and patient can be turned on his side, thus lessening the danger of hypostatic pneumonia.

(3) Adhesive strips on the body more comfortable and more efficient than counter pressure in the groin or on the perineum.

(4) Pain during application of the apparatus and during the period in bed is relatively slight.

(5) One attendant can manage the patient for every necessity.

(6) Well adapted to the application of any cast for hip, body, or femur.

Dekum Building.

ADENOSARCOMA OF THE LEFT KIDNEY IN A YOUNG CHILD; LANGENBUCH'S NEPHRECTOMY; RECOVERY.

By VICTOR C. PEDERSEN, A.M., M.D.,

NEW YORK.

The following report of a case of adenosarcoma of the kidney in a young child will be of interest and it is hoped, a valuable addition to the literature on the subject:

E. V., white, U. S., three years and five months old, referred by Dr. Ira B. Terry, through whose permission this report is made.

Family history negative as to neoplasm of any form so far as the mother knows. Father died of Bright's disease. Mother is in good health. There

A. *B.*

Fig. 1.—Before operation. *A*, Left quarter view, showing the protrusion of the tumor to the left and front, and extension upward and downward; the hollow back is indicated in the right line. *B*, Front view of tumor mass.

is one other child in the family in moderate health. Mother's father died of asthma; mother's mother is living and well in old age. Two brothers on the mother's side died as infants of diseases unknown. Father's father is now dying of dropsy, probably renal in origin. One brother died in infancy of unknown cause; another is living and well. Aside from the foregoing medical diseases of the kidney there have been no surgical lesions of the kidney in any immediate or remote members of the family so far as the mother knows.

The past personal history of the child states that

Fig. 2.—Front view. Tumor divided along its left border, as well as possible toward the hilum. Total destruction of kidney substances is shown, together with cavities, thin walls in places, and degenerated tissue and bloodclots both within the tumor substance and lying about on the table.

she has always been well and seems to have grown as rapidly as most children and to have shown the usual childish tendencies for play and ambition. There have been no serious sicknesses.

The present personal history reveals that for the first time the child passed blood in the urine in large quantities on December 1, 1910. The bleeding continued for a few days and then subsided. It recurred on January 1, 1911, without known cause as before and again lasted two or three days; the quantity of blood was on this occasion also large. Ordinary medicinal measures soon quieted it. The child remained apparently well and in her normal spirits until April 28, 1911, when she complained of pain in her left side. The mother examined her abdomen and found a lump which Dr. Terry diagnosed as renal in origin and summoned the writer in consultation. It was an easy matter to verifiy the diagnosis.

Physical examination showed a tumor perceptible in the erect and lying down positions. The former

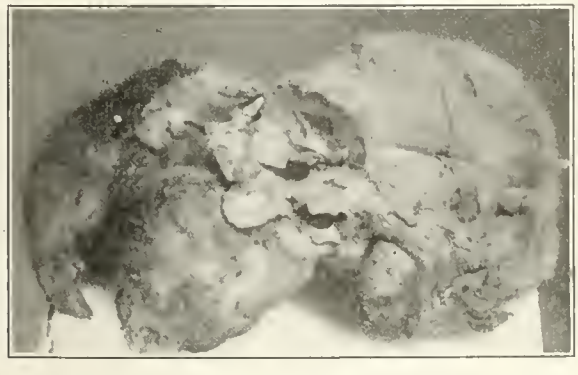

Fig. 3. Posterior view. Kidney substance has been cut across horizontally to secure specimen, thus opening the pelvis. A small portion of the right border and upper pole remained. The mass grew from the anterior surface and upper poles chiefly. The rupture in the thin walls of the tumor are shown in the lower left hand region.

is well shown by the photograph in Fig. 1. On inspection it was noticed that the abdominal muscles on that side of the body were relatively quiet in breathing and that the child on standing threw back her shoulders and hollowed her back much as a woman does when advanced in pregnancy. The

child's mental attitude was one of unusual docility and quiet. On palpation the mass was traced readily into the left flank and was separable from the free border of the ribs. It was not particularly tender although the abdominal muscles resisted the examination somewhat.

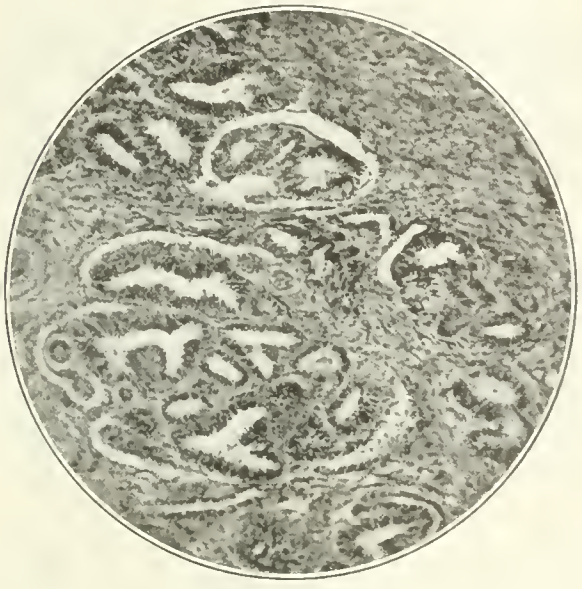

Fig. 4.—Microphotograph showing typical adenosarcoma.

The tumor was soft and rather freely movable from the flank forward but not from above downward, perhaps because one could not get the hand beyond either pole. On percussion the colon was found to pass over the tumor from above downward in good correspondence with the main axis of the mass.

In the flank was another zone of tympanites which the writer regarded as referred from the small intestines gathered together on the right side of the tumor. The point was raised, however, by Dr. Terry and by my chief, Dr. Page, at the People's Hospital, that this sign possibly indicated a coil of small intestines on the left side of the tumor. At the time of the operation the former condition was found to exist. The patient was admitted to the People's Hospital on April 30, 1911. It was determined to test the efficiency of the opposite kidney before proceeding to remove the diseased kidney, which, of course, was regarded as sarcomatous in all human probability. An effort was made to cystoscope the child under local anesthesia, which was neither satisfactory nor successful. The following day, under ether narcosis, a reasonably satisfactory cystoscopy was performed.

The mouth of the left ureter was found to be slightly larger, more patulous, and redder than the right but quite within the range of a normal ureteral mouth except for the fact that it was discharging no urine. The right ureter was found to be rather large for a child and to deliver the natural quantity of urine. A half-gram of indigo carmine was injected into the buttock. Its delivery in the urine began in practically forty-five minutes. Long before this time the anesthesia was stopped. It was considered inadvisable to determine whether the left kidney was excreting at all or not. The test was regarded as demonstrating as reasonably well as necessary the fact that the right kidney would do the work of the body.

The child was allowed to rest two days and then, under ether narcosis, Langenbuch's nephrectomy was performed in the following manner: The abdominal cavity was opened along the left linea semilunaris. It was found necessary to enlarge the original incision both upward and downward in order to deliver the kidney easily.

The abdominal contents were found only on the right side of the mass except the colon, which passed from above downward, corresponding with its long axis. The parietal peritoneum was divided about one inch away from the colon from above downward toward the left. This leaf of peritoneum was rapidly peeled off most of the tumor excepting where it was densely adherent above. It was clamped to the skin every inch or more to shut off the peritoneal cavity. The other leaf was dissected less freely from the abdominal wall and clamped to the skin, once above and below. It would have been better when this dissection was made if the peritoneum had been stitched instead of clamped. The intestines of the child were filled with gas and caused a great deal of trouble by passing between the clamps, especially below.

The kidney was then enucleated from its bed, just as rapidly as possible, first behind, then below and above, and finally in front, where it was adherent. Here the tumor was distinctly softened, and, notwithstanding all reasonable gentleness, ruptured and discharged gelatinous or myxomatous material, which was fortunately caught probably completely upon the gauze pads. After this the peritoneum was pushed away fairly successfully with gauze pads, the pedicle isolated, clamped twice, divided, and the tumor removed. The dissecting, clamping, and division of the pedicle caused shock, from which the child slowly rallied.

Proximal to the clamp on the pedicle at this step of the operation another thin-jawed clamp was placed briefly to control the vessels. In the end of

A. *B.*

Fig. 5.—After operation. *A* and *B* correspond as nearly as possible with the same pictures in Fig. 1.

the stump the artery was isolated and tied, likewise some of the larger veins. The whole stump was then whipped over with a running suture from end to end, drawn tightly. The two ends of this suture were again tied together, massing the stump rather carefully. The distal clamp was then removed and

finally the proximal clamp, while the suture ends, left long, kept the stump in view. No bleeding occurred. The bed of the tumor was then wiped clean, washed with normal salt solution, which was likewise used to clean the exposed portion of the intestines. As there was no ooze, no drainage through the loin or otherwise was employed.

The abdominal wound was closed with through and through silkworm gut sutures every half-inch from end to end. The skin was carefully adjusted to itself and large dressing applied with adhesive plaster passed almost fully round and round the body rather tightly for support. The child was returned to bed in decidedly poor condition. All the usual methods of stimulation and support were adopted in the ward to restore the child to health. After three days of gravest doubt as to the outcome she finally rallied and made a full recovery. The wound healed by primary intention. The gross specimen is rather well shown by Fig. 2. When the kidney was divided it was found that hardly any tissue even approximating normal in appearance remained. Nearly everywhere the specimen was degenerated into gelatinous material. It came away in formalin, hard, and occupied nearly an inch in the bottom of a quart jar. The cavities left in the kidney come distinctly into view in Fig. 3, as does also the thinness in the wall at the upper pole of the kidney where the rupture of the cystic condition occurred.

The microscopical diagnosis was made for me by Dr. Charles J. Stebbins, pathologist of the People's Hospital, to whom I am indebted for the courtesy of the examination and for the microscopical photograph shown in Fig. 4. He pronounced the growth adenosarcoma.

This case was admitted to the People's Hospital in the service of my chief, Dr. Kingman B. Page, to whom I am indebted for the kindly and friendly services and professional cooperation in the matters of the foretreatment, operation, and aftertreatment of the patient.

While there is nothing especially novel in the case, it seems well to contribute it to medical literature. Undoubtedly the child will go the way of other sufferers in this disease. Fig. 5 shows her condition after the operation.

A CASE OF GIANT CELL SARCOMA TREATED SUCCESSFULLY BY RADIUM.*

By WILLIAM BENHAM SNOW, M.D.

NEW YORK.

The patient, Mr. J. J. L., first came under my observation on November 28, 1909. At this time he presented on the outer aspect of the left hand, extending from the middle of the outer phalanx of the hand to above the ulnar prominence of the wrist, a marked swelling which had been incised about midway between the two extremities of the growth and from which exuded a serous fluid. The tumor was very prominent and had been painful prior to the incision being made. The growth had started from a small indolent tumor which had been present for about four years and had taken on a rapid development following a long course of typhoid fever, commencing about two months prior to the time it came under my observation.

* Read before the New York Society of Radiology and Physical Therapeutics at the New York Academy of Medicine, February 24, 1911.

The patient had, by the advice of his family physician, Dr. James T. Meehan, been admitted to the St. Vincent Hospital in the service of Dr. George D. Stewart. Through the courtesy of Dr. Stewart and Dr. Meehan I am able to present the report of two microscopical examinations made of sections of the tumor in the pathological laboratory of Bellevue Hospital, which is as follows:

"Pathological Report on Specimens from J. J. L.—The two specimens from the hand of this case show microscopically the lesion of a sarcoma. In the first specimen the picture is that of a fairly cellular fibrosarcoma, and its point of origin cannot be determined. The second specimen, however, shows it to be a sarcoma with a large number of giant cells, such a tumor as frequently arises from the periosteum. Signed, B. C. Crowell."

In a letter to Dr. Meehan Dr. Stewart expressed it as his opinon that an amputation of the arm at the elbow was advisable, providing Dr. Meehan and others concurred in that opinion.

The patient was then referred to me, and I assured him that the use of radium would not interfere with the performance of a subsequent operation if it did not succeed, and it offered a prospect of saving his hand. After consulting his physician, he decided to submit to the radium treatment.

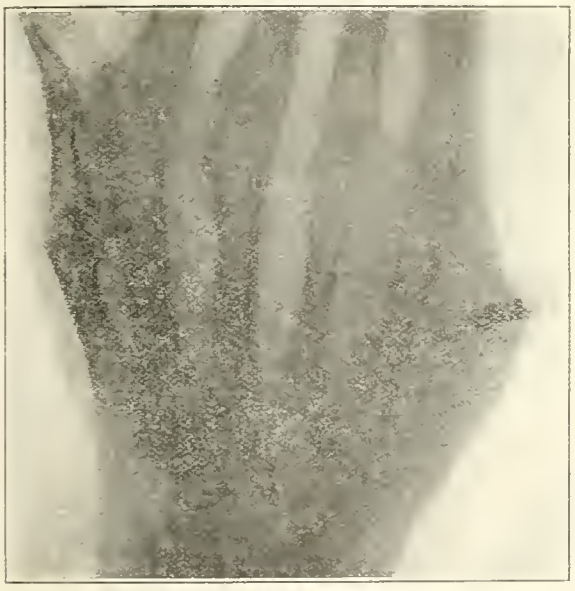

Fig. 1. Cut showing the tube of radium in position in the hand; the radium showing at the outer end of the tube.

On November 26 I introduced a glass tube containing radium bromide of 50,000 radioactivity into the tumor. The bone lay as shown in the cut, across the first metacarpal bone. It was left in this position for eight days and then the position was changed so that the long end of the tube containing the radium should lie in proximity to the cuneiform bone. The patient was instructed to hold the hand in such a position that the radium would gravitate to the inner end of the tube.

It was left in this position for three days longer, making in all eleven days that the tube of radium was in the hand. The tissues were so friable that we were able to place the tube in position with ease and without causing the patient great discomfort. At the end of the eleven days the surface over the whole tumor presented a pinkish appearance, which was the effect of the radium acting upon the skin from within the tissues. This effect was the indication to withdraw the radium.

At this time there was also considerable reaction taking place in the forearm extending to the elbow with the evidence of infection or toxemia, probably the latter, due to the destruction of the malignant cells. This action, however, did not involve the glands or tissues above the elbow.

Until February 2 we gave local applications of radiant light and heat from a high-candle power lamp, and direct d'Arsonvalization with the high-frequency current to the forearm and hand for the purpose of increasing the local resistance by maintaining active hyperemia in the parts.

In the hand where the radium had been placed, immediately surrounding the site occupied by the tube as shown in the skiagraph, a tubular core of tissue had formed, probably due to the action of the β (beta) rays, which would not slough away. This tissue was evidently sterile of germs, as no local reaction or suppuration occurred.

On February 2 I had the hand opened and curetted by Dr. Herman Grad. A microscopic examination was made of this tissue under the direction of Dr. Grad at the Women's Hospital, the report

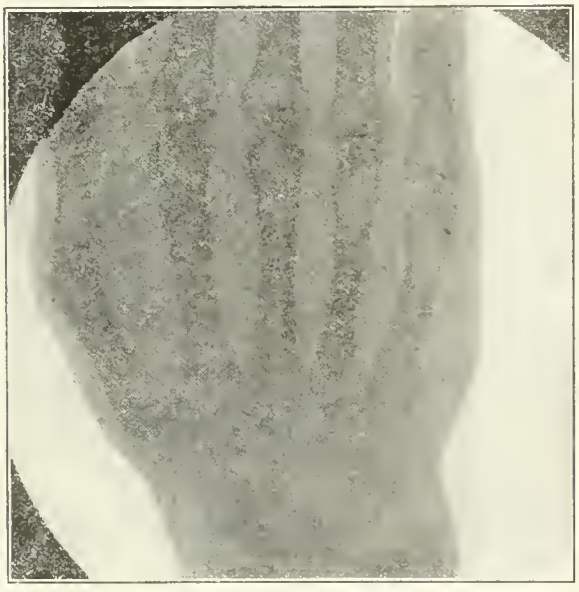

Fig. 2.—Showing the condition of the hand and bones at the present time.

of which was as follows: "The specimen removed from the hand of J. J. L. shows microscopically a mass of broken-down tissue. A frozen section made of the specimen does not show the structures of the cells clearly. The stained section, however, shows the cells to be large, with large nuclei that take the stain well. The field shows a marked round-cell infiltration with many blood-vessels. The vascularity of the tissue is a decided feature with the tissue. The specimen does not show any cells resembling those of a sarcoma. The appearance of the mass is not that of a malignant tumor."

The wound then healed rapidly and the arm and forearm gradually resumed their normal condition and have so continued for one year. There is now no evidence, as will be seen, of any active process in the tissues, and the skiagraph (Fig. 2) taken recently shows the present condition of the bones of the hand.

This case, with others that have been treated by me, and those reported by other writers, demonstrate the selective action of radium on the sarcoma cells, and we believe that if radium were used more heroically than it often has been, there is a time in most of these cases of giant-cell sarcoma when they could be promptly cured.

Another thing demonstrated in these cases is the peculiar action of the β (beta) rays upon the tissues immediately surrounding the glass radium tube when left for some time in the tissues. This can be obviated by placing the glass tube within a tube of aluminum of the requisite thickness to absorb the β rays.

329 West Fifty-seventh Street.

A CASE OF TRUE CONGENITAL UNILATERAL HYPERTROPHY.

By ARTHUR J. DAVIDSON, M.D.,

PHILADELPHIA, PA.

ASSISTANT ORTHOPEDIC SURGEON AND CHIEF OF THE ORTHOPEDIC OUT PATIENT DEPARTMENT, JEFFERSON MEDICAL COLLEGE HOSPITAL; ORTHOPEDIC SURGEON, M. A. LOEB DISPENSARY, JEWISH HOSPITAL.

Because of its interest from the diagnostic standpoint, as one of the unusual types of congenital abnormalities, the following case is reported:

The patient, G. G., a female infant, age one month, of Russian Jewish parentage, was first seen at the Orthopedic Out-Patient Department of Jefferson Medical College Hospital, December 27, 1910. The following history was obtained by Dr. Warren B. Davis, resident physician: The father of the child is twenty-one years of age, and the mother is nineteen. They are both in good health. The mother has had no illness during pregnancy.

Fig. 1.—Congenital unilateral hypertrophy.

They have been married one year, this being their first and only child, born at full term, spontaneous delivery. The child did not breathe well for some time after birth. The mother's supply of milk being inadequate, the patient has been bottle-fed from the beginning. She has taken her nourishment poorly, and often vomits after feeding. The mother noticed that the left eye was inflamed on the day following birth; this inflammation has persisted to the present time, although the eye has been washed twice daily with boric acid solution by the mother. One week ago, a small abscess developed over the left super orbital ridge. The child has been very restless and cries a great deal. She is a very small, poorly nourished child, weighing only six pounds. She has not grown or gained any in weight since birth. Shortly after birth, it was noticed that the right leg and foot were considerably longer than the left, and it was for this reason that the child was brought to the hospital.

Examination—Eyes: The left eye is held tightly closed and has a purulent discharge. The cornea does not show ulceration. The right eye is only

slightly inflamed, with no discharge. There is a small superficial abscess one-fourth inch in diameter over left super orbital ridge. Ears and nose: Negative. Mouth: There is evidence of a begin-

Fig. 2.—Congenital unilateral hypertrophy.

ning stomatitis. The tongue is coated in patches. There are several superficial ulcerations. Thorax: The bony framework is slightly prominent, poorly formed, but symmetrical. Lungs: The lungs are resonant throughout. Heart: The heart sounds are deficient in the muscular element. There are no murmurs. Abdomen: The abdominal walls are thin and slightly distended. Liver: The liver is relatively large. Upper extremities: The upper extremities are symmetrical. They show evidence of poor nutrition, but are otherwise negative. Lower extremities: Both hips are freely movable in all directions. The right leg and foot are appreciably longer and larger in circumference than the left. There is a marked outward bowing of the femur and tibia of each leg. The comparative measurements of the legs are as follows:

	R	L
Circumference of thigh at groin	13⅜ cm.	12½ cm.
" " " " middle	11 "	9½ "
" " calf	9½ "	8¼ "
" " ankle	8½ "	6¾ "
" over dorsum of foot	7½ "	7 "
From anterior superior spine to internal malleolus	19¾ "	16½ "

Radiograph: A series of radiographs were taken by Dr. W. F. Manges. The child, in each instance, was firmly strapped to the radiographic plate, in order that each extremity should be at the exact relative distance from the plate, to obviate any erroneous impression that might exist from shadows thrown from different distances. The upper extremities, thorax and abdomen appear to be normal. The hips are symmetrical and normal in appearance. There is marked enlargement on the bones of the right lower extremity. The femur, tibia and fibula share uniformly in this enlargement. The enlargement of the foot appears to be due mostly to a hypertrophy of the soft parts. There is a distinct outward bowing of the femur and tibia of both legs. The exact measurements taken from the radiographic plate, which are accurate, in consideration of the fact that both limbs were in the same relative position to the plate, are as follows:

	R.	L.
Length of shaft of femur	8.4 cm.	7.7 cm.
" " " " tibia	6.4 "	5.8 "
" " " " fibula	6.5 "	6.1 "
Breadth of lower extremity of femur	2.0 "	1.75 "
" " upper " " "	1.2 "	1.1 "
" " " " " tibia	1.5 "	1.3 "

The above figures show a relative symmetrical enlargement of the bones of the right lower extremity, with a corresponding enlargement of all of the soft parts of the limb. The temperature, sen-

Fig. 3.—Radiograph in a case of congenital unilateral hypertrophy.

sations and reflexes are normal in both limbs. There is no evidence of pain or tenderness. There are no impaired movements of any part of the body, nor is there any unilateral involvement of the upper extremities, face, cranium or chest. The tissue seems to be equally firm in all of the extremities and the general contour of the limbs is undisturbed. In view of the facts, therefore, that there is no evidence of atrophy in any part or parts of the anatomy, no disturbance in function, temperature, reflexes or sensations, and that all of the tissues of the limb in question uniformly participate in the overgrowth, without any disturbance in contour, the above case may be considered as one of true, congenital unilateral hypertrophy.

200 South 12th Street.

THE OPERATIVE TREATMENT OF ACUTE APPENDICITIS.*

By JOSEPH B. BISSELL, M.D.,
NEW YORK.

When your president asked me at rather short notice to read a paper before your society he assured me it need not be long as the discussion was much more important, and would be of a much greater extent than the paper needed to be. It was for this reason that I have the temerity to take up so well-

*Read before the Society of the Alumni of St. Vincent's Hospital, March 8, 1911.

worn and trite a subject as the operative treatment of acute appendicitis. I wish to draw your attention to a few only of the many phases of this rather voluminous subject. The ideas which no doubt most of you entertain on the subject are doubtless more instructive than those which I will endeavor to put, in a rather disconnected way, before you. The scope of the paper will be confined to acute attacks, whether catarrhal, purulent, or gangrenous, and whether the inflammatory condition is limited to the organ itself or has extended to the general peritoneum. The symptoms of pain and tenderness in the right iliac region, rigidity of the right rectus muscle, vomiting, chill, temperature, rapid pulse, combined with the typical blood picture men an attack of inflammation inside the peritoneal cavity, which may or may not lead to suppuration, perforation, blood infection, and possibly death of the subject invaded. If the classical type of the disease presents itself it is easy to differentiate, and the merest surgical tyro can make a proper diagnosis. All sorts of variations from this type occur. From opposite points of view, as the different symptoms appeal to one's mind, the internist and the surgeon may argue as to the necessity of immediate or future operation, or no operation at all. We know certain of these cases do recover without operative interference, but we have no absolute means of saying whether in a given case this particular patient will get well without operation or whether he will go on to abscess, perforation, or a degree of inflammatory action and infection irreparable when at last operation is permitted. We know this much, however, that operation early enough in every case of this disease results in recovery. If this is so, and most of you will acquiesce as to its truth, why hesitate to advise operation after the diagnosis is made? In other words the surgical axiom follows, that the time to operate on appendicitis is as soon as the diagnosis is presumably certain.

Having decided that practically every case of acute or recurring appendicitis should be operated upon, the surgeon, in doing an appendectomy, should pursue his work with the utmost care, with good judgment, and with the latest methods of technique, an up-to-date knowledge of the pathology of the disease, of the powers of recuperation of this part of the body, and of the physiological and constitutional reparative ability of the human body in general, and of the special patient under consideration in particular. The operation should be done rapidly, carefully, and with the latest and best methods. Each surgeon probably has his own special technique. Personal equation counts for much in any operation involving the opening of the abdominal cavity. Whichever method of removal of the appendix is chosen it should be the one with which the operator is most familiar and at which he is most skilful and adept. He may have his own personal way of doing this operation, and his reasons for having special technique; if so, it will be derived from long study and experience, and will undoubtedly produce good results for that reason. Simplicity, delicacy in handling the tissues, and rapidity of action are the three main factors in a successful appendectomy. The method in which one is trained, if based upon good technique, as well as surgical and anatomical knowledge, is the safest and best for the patient. A large operation wound is not necessary, and while not absolutely contraindicated is now seldom made. In all surgical procedures the less the tissue disturbances the better the results obtained. The period is within easy memory of the youngest practitioner here when it was considered good surgery to make large incisions, to do extensive dissections, and to wall off the intestines with large quantities of gauze pads. It was thought absolutely necessary to rigidly inspect the entire suspected peritoneal area, or even the whole peritoneal cavity, and remove all local evidences of inflammation. The cavity was washed out or sponged, or wiped or irrigated with the utmost care and patience, thus taking a long time at the expense of the local and general vitality and resistance of the patient, and to his great detriment.

Lavage as a routine treatment, even if the abdominal cavity is full of sero-pus, is no longer employed. The use of large dry pads, particularly the use of coarse gauze sponges to wipe the abscess cavity and the surrounding tissues, is at present omitted in the operative technique. There is no question but that most of these procedures did great harm: They not only insulted the peritoneum, and impaired its absorbing and repairing ability, but by means of these painstaking, though foolish, measures the operation was often prolonged beyond the limits of the patient's endurance. All irritation of the intestinal covering is to be avoided and the visceral contents of the peritoneal cavity as well as the peritoneal surfaces are to be protected in every way from injury and exposure. Faith in the ability of the peritoneum to take care of much of the inflammatory results of disease has been restored. Every attempt is made to preserve the normal function of the epithelial surface of the peritoneum. Assistance, and not hindrance, is to be afforded to nature in her efforts to cure the infection. As much as possible, pernicious interference with the pathological conditions in the abdominal cavity is proscribed, as likely to handicap or prevent the natural reparative processes. Fortunately for the good name of surgery and for the victims of this disease modern teaching and experience have modified the former vigorous but ill advised efforts so that the tissue destruction and the injury to the vitality of the patient caused by a present-day appendectomy is reduced to one-quarter of that of a few years ago, with a proportionate reduction in morbidity and mortality. Careful handling of the tissues, rapidity in operating, skilful dissection, and following the cleavage layers are component parts of the modern plan of procedure from beginning to end of the operation. The removal of a diseased appendix should be performed as simply and as rapidly as is consistent with thoroughness and safety. These precautions are, of course, not new. They are mentioned, however, to show what is believed to be the reason for the present low percentage of deaths from this operation. Freedom from mortality is no longer pointed out as remarkable. The report of a death as the result of, or following an appendectomy, is received with uplifted eyebrows, and requires an explanation, if not to the family and friends, at least to the surgeon himself. The following description seems best to fulfil, in a general way, the requirements for the removal of a pathological appendix. Variations from this occur, according to the surgeon operating, according to the location and extent of the disease, and according to the pathological findings. Preceding the operation the skin of the region is iodinized in the usual manner, now familiar in hospital practice. On the dry unscrubbed skin of the lower abdomen ordinary tinc-

ture of iodine is rubbed with a piece of gauze on an applicator. No moisture is left on the skin for some time preceding this application. If hairs are to be removed by shaving this should be done several hours before the operation. No subsequent attention is paid to the skin after it has been iodinized, and the operation is at once proceeded with. The incision to be selected will depend not only upon the surgeon's inclination, but also upon whether a tumor or abscess be present. In the latter event, if the diagnosis is obvious the indication is very simple; the abscess is opened and drained, incision being made at its most dependant portion; if it is possible the appendix is removed through this incision. If the appendix does not present itself, and there is difficulty in finding it, no prolonged attempts should be made to discover it and excise it. Free drainage, if necessary, by a counter opening is instituted, while the appendix may be left to be removed at a later period after the abscess has healed up. If a tumor only is present, the surgeon may exercise his discretion as to whether he cuts down directly over the tumor, or makes a typical incision for the removal of the appendix. The ideal incision wound for an appendectomy must be considered from the anatomical, the mechanical, and the surgical standpoint. From an anatomical standpoint all injuries to nerves and important vessels should be avoided. From a mechanical point of view we should never make an incision which cannot be accurately and completely repaired, so as to reestablish the abdominal wall to its normal condition. Surgically, however, we are forced to take into consideration the acute or chronic, pathological situation which calls for interference in order to save the life or health of a patient with only incidental regard for the two former viewpoints. Taking these facts into consideration it is no wonder that appendectomy incisions are many and various. From an anatomical standpoint, as regards the belly wall itself, the McBurney incision is almost ideal. Its greatest fault, and one which we must take into our calculations, is that if drainage is necessary its advantages are at once lost by the necessary destruction of tissue to meet that indication. The old oblique incision over the McBurney point is a mechanically faulty one because it cuts across the internal oblique and transversalis muscles, destroying their usefulness, and leaving the patient predisposed to future hernia. The median incision, like the McBurney cut, avoids the nerves, and is in a location where there are few vessels, none of them important. It is particularly valuable in the female subject, where there is an even chance, or more, that the pelvic viscera may be involved, and need attention. Various other incisions, to which the name of the surgeon who first employed them is attached, are said to have special advantages, and are made use of at times. The Gil-Wylie and the Weir incisions are among the best of these. The incision which I have selected for years, and in the use of which I am the most skillful, has been by a recent anatomical writer condemned as anatomically so faulty that he wonders at its employment. He advances a number of anatomical reasons why it should never be used. The reasons are, I am bound to say, very good ones, and yet practically in my own, and the experience of many other surgeons, the method has been entirely satisfactory. Among other objections which Dr. Tobie, the anatomist in question, advances against the use of this incision, are the following: "With the exception of the rectus muscle it cuts across the fibers of every layer through which it passes at an angle of from 45 to 90 degrees. But this is not its only fault. The sheath of the rectus may properly be considered a conjoined tendon of the internal oblique and transversalis muscles with its insertion at the lines alba. A cut across this tendon is necessarily followed by a retraction of its proximal side—therefore the wound gapes. Nor does the rectum, by its contraction, tend to produce closure, but rather the reverse, through a buckling action produced by force exerted on the upper and lower angles of the wound, pulling them towards each other. Moreover, unless the incision is made short, and fortune favors the selection of its site, it will sever one or more motor nerves and destroy the function of a part of the rectus muscle. Accordingly then, instead of urging as one of the advantages of this incision the fact that it may be lengthened, its description had better be supplemented by the caution 'it should not be lengthened.'"

This incision is known as the Battle, or the Kammerer. It is a vertical cut about two and a half to three inches long over the outer border of the rectus muscle, roughly speaking about a finger's breadth within its edge. It is continued through the outer sheath to the muscle. The wound is retracted towards the median line, and its inner sheath, with the peritoneum, divided somewhere nearer the middle line of the body than the anterior sheath, so that where the two layers are repaired they are not in the same line with each other. The rectus muscle of course lies between them. In spite of all the anatomical objections given above, the result of this operation in my hands has been uniformly successful. As a result of it there has been no appreciable loss of function, or of sensation, in this location. There has been no hernia following it, and even when it has been necessary to institute drainage, because of pus or an abscess, the result has been equally good ultimately.

The treatment of the stump depends somewhat on the special technique of the surgeon operating. The diseased appendix should be removed quickly, and left as harmless as possible. A double ligature carried through the meso-appendix close to the base is divided into two ligatures. The first one is tied around the root of the mesentery, one end being left free temporarily, and the other cut away close to the knot. The appendix is crushed close to its base by a hemostat the other ligature remaining in situ is now tied over this crushed portion, and held firmly but gently in a hemostat. One of the ends of this ligature is also cut off close to the tie. The appendix is grasped by another hemostat about a quarter of an inch away from the first, for protective purposes, to keep any contents of the diseased organ from infecting the parts. The thermocautery now divides the appendix close to the first hemostat, practically burning all the tissues between the two instruments, which are removed, and the knots brought together by tying the ligature ends left for this purpose, bringing the stump of the appendix to the stump of the mesentery, and in this way burying it. All this is done much more quickly than it takes to describe it, and is a safe, simple, and rapid way of disposing of the appendix stump. If drainage is to be instituted because of oozing, or because of a purulent or gangrenous appendix, these two ligature ends are made use of for that purpose as follows: A needle is threaded on to either one

of them, which by this means is brought through the end of a cigarette drain cut long enough to project out of the lower end of the wound. The two ligature ends are then tied together, carrying the cigarette drain down to the base of the appendix and the base of the mesentery, so that it projects from this deep seated location down in the abdominal cavity, out through the lower end of the wound, thus draining the affected peritoneal surfaces. The loosening of the catgut ligatures takes place in four or five days, or more, depending on the size of the thread used. It is usually the No. 0 or the No. 1 plain sterile catgut. If drainage is not necessary, as in the majority of interval appendectomies, the wound is sewn up in three layers with a single continuous catgut suture in each layer. The upper and outer layer being plain sterile catgut, and the middle tier used in the superior sheath of the rectus chromicised catgut. The skin and subjacent fascia are brought together by a subcuticular suture. The ends of this suture are left long, and tied over a thick square pad of gauze, thus pressing the edges of the cut into accurate apposition and keeping them there. The dressings are changed regularly on the seventh day, when the incision is found to have left a fine line of union which hardly shows except for a little redness. This method of closing the abdominal wall gives three tiers of sutures, so placed that they are not exactly over each other, with a thick pad of muscle, the rectus between the two lower layers. The patients are allowed to sit up on the ninth day, out of bed on the tenth, and leave the hospital on the eleventh or twelfth day. The above is a description of the routine operative practice of the writer's in use for several years, and includes the observations in several hundred cases. The mortality is practically *nil*, being less than one-quarter of one per cent. In spite of the anatomical objections, the practical result of this method has been to give a solid belly wall, with practically no scar, no tendency to hernia, and no complaint such as we might expect from non-union of divided nerves, interference with blood supply, or from fascial faults. In all my cases I have never had an abdominal hernia following this operation properly carried out, even where the necessity for drainage has compelled a secondary and long delayed union of the incision.

BRILL'S DISEASE.*

REPORT OF CASES.

By LEON LOURIA, M.D.,

BROOKLYN, N. Y.,

ATTENDING PHYSICIAN TO THE JEWISH HOSPITAL.

At a meeting of the Section on Medicine of the New York Academy of Medicine, held in January, 1910, Dr. N. E. Brill presented a paper embodying the results of a clinical study of 221 cases of an acute infectious disease of unknown origin. It was his opinion that this disease represents a clinical entity distinct from that of any disease hitherto described. This conclusion was based upon observations made during a period of twelve years at the Mount Sinai Hospital of New York City. The alleged discovery of a new disease is usually received with an attitude of scepticism. It was quite natural that this paper aroused considerable discussion. Even though the reported cases presented a definite clinical and pathological picture, many clinicians were loath to regard this disease other than as an atypical form of typhoid fever. The conclusions arrived at by Dr. Brill, who is known to be a careful and painstaking observer, could not be passed over without further investigation, particularly since these conclusions were based not on casual observation, but on persistent and careful work extending over a period of twelve years.

A committee of the Section of Medicine was accordingly appointed to investigate the evidence justifying this new addition to our nosology. This committee presented the following report at the meeting of the Section of Medicine in December, 1910: "1. The cases described by Dr. Brill present a fairly uniform symptomatic picture and seem to the committee to be entitled to recognition as a clinical group. 2. The clinical picture is quite distinct from that of typhoid fever. 3. It seems conclusive that they are not cases of infection with the typhoid or paratyphoid bacillus. 4. The evidence at hand does not seem sufficient to decide whether these cases represent an atypical form or some already recognized disease other than typhoid or paratyphoid fever, or are instances of a disease hitherto unrecognized."

Dr. Brill published a full report of his observation and conclusions in the *American Journal of Medical Sciences*, April, 1910. One cannot fail to be impressed with the fact that the conclusions of the author are fully warranted. This article awakened the interest of the attending physicians in the medical service of the Jewish Hospital of Brooklyn, who recently have been on the alert for cases of so-called Brill's disease. During the summer and fall we had the opportunity of observing 18 cases of this disease in our service. In brief, the disease in question is an acute infectious disease of a short duration of 12 to 14 days with a sudden onset, a rapid critical fall of temperature, and a marked eruption over the entire body. I shall present the histories of but three cases, which strikingly illustrate the clinical picture of this disease.

Case I. M. S., 28 years of age, male, born in Russia; salesman. Entered the hospital August 16, 1910. His previous history had no bearing on the present illness. Five days before admission he was suddenly taken ill with a severe headache, fever, and marked prostration; his bowels were constipated and there was no epistaxis. The following day the patient had a prolonged chill followed by high fever; the headache still increased in severity and the prostration became more marked. These symptoms continued without abating when he was admitted to our service. His chief complaints were severe headache, fever, and weakness. He looked very ill. On examination, heart and lungs were negative; the abdomen was normal; the spleen was not palpable, though the area of dulness was slightly increased; the conjunctivæ were injected; the tongue was heavily coated with a white fur; there was a profuse rash extending over the anterior and posterior parts of the chest and abdomen and over the upper and lower extremities. The rash was of a pinkish blue color, of a maculopapular character; some of the papules were slightly raised; they did not disappear on pressure though some faded when pressed upon; in some places the eruption was discrete, irregular in shape and about two or three mm. in diameter, while in other places it was somewhat confluent, resembling morbilli. The temperature on admission was 103.6° and continued

*Read before the Kings County Medical Society, April 18, 1911.

with slight fluctuations until the morning of August 20, the tenth day of the disease, when it reached 104.2°, and then steadily fell to normal on August 23, the thirteenth day of the disease.

The pulse was 118 and respiration 24. The examination of the blood on admission showed 14,600 leucocytes with 80.4 per cent. polynuclear cells. On the 20th the blood count was the same and on the 24th showed 17,000 leucocytes and 73 per cent. polynuclears. The diazo reaction was negative on repeated examinations The Widal reaction was negative on eight examinations made every second day. A blood culture was made August 17, the 7th day of the disease, and gave no growth of organisms. On the 10th day of the disease, simultaneously with the drop of the temperature, the rash began to fade, became indistinct, and on the 12th day, when the temperature came down to normal, the rash disappeared. The convalescence was uneventful with the exception of being slightly protracted in this case, which is explained by the fact that this patient suffered a very severe infection. This was the most typical and most severe case of Brill's disease that came under our observation.

Case II. J. T., 25 years old, male, born in Russia; furrier; was admitted to the hospital September 8, 1910, on the 6th day of his illness. He had typhoid fever at the age of 17, when he was sick for four weeks; otherwise his previous history was negative. The present illness began suddenly with a chill, fever, constipation, pain in the abdomen, and vomiting (the patient vomited once) followed by severe frontal headache and marked prostration. There was no epistaxis. Physical examination of the organs of the chest and abdomen was negative; there was a marked rigidity of the neck and a moderate Kernig sign was present. The skin presented on the abdomen, back, and extremities a profuse rash, which was mottled, discrete in some and confluent in other areas; it was maculopapular in character; the spots were 2 to 4 mm. in diameter and some disappeared on pressure. The temperature on admission was 103.8°; the pulse, 120, and the respiration, 22. The blood showed 10,200 leucocytes, 62 per cent. polynuclears. Diazo reaction was negative. Widal and other agglutination tests as to paratyphoid and colon bacilli were negative on three examinations; the blood culture was sterile. The blood-pressure was 105. The temperature did not vary much until the tenth day of the disease, when it began to fall by crisis and became normal on the morning of the 12th day of the disease. With the drop of the temperature the rash disappeared and the patient rapidly improved and was able to leace his bed on the 4th day after the temperature became normal, on the 16th day of his disease. The further course of this case was uneventful.

Case III. H. W., 26 years old, born in Russia; tailor; admitted on October 23, 1910, on the 6th day of his disease. His previous history was negative. The onset was sudden, with a chill and a severe headache which could not be relieved by drugs. The headache increased in severity on the following day; the patient had chilly sensations and marked prostration, and an occasional cough and some epistaxis the first few days after the onset. The examination of the organs of the chest and abdomen proved negative; there was a marked eruption scattered over the chest, abdomen, arms, thighs, and back; it consisted of small red spots of a maculopapular character, which did not disappear on pressure. There were a moderate rigidity of the neck and a moderate Kernig sign. The temperature on admission was 103°, which gradually rose to 104° and 104.6° on the 8th day of the disease; it then rapidly fell with slight exacerbations and became normal on the morning of the 11th day. The blood examination on admission showed 12,000 leucocytes and 87½ per cent. polynuclears; on the 10th day the leucocyte count was 14,800 with 86½ per cent. polynuclears. The diazo reaction was negative on repeated examinations; blood culture was sterile. The Widal reaction was negative on six occasions. On the 9th day the rash was still present and gradually fading. On the 11th day the rash had almost entirely disappeared, but some spots could still be seen and the pigmentation was quite marked. On the 17th day the patient developed a phlebitis of the left femoral vein, from which he recovered in a week. The blood-pressure was 100, gradually rising when the temperature became normal, and reached 125 mm. of mercury on the 22d day of his disease.

The above three cases illustrate typical cases of Brill's disease. While the number of cases I have personally observed is limited to 18, I shall endeavor to tabulate them and discuss each symptom separatively.

Sex of patients: There were 12 males and 6 females. The larger percentage of males has been also observed by Brill. Nativity: Russia heads the list with 14; Roumania has 2 cases; Austria, 1; United States, 1. The preponderance of Russians is explained by the fact that the largest number of patients applying to the Jewish Hospital of Brooklyn are born in Russia. Months: The summer and fall apparently are favored by the infection; 7 cases occurred in August, 4 in July, 2 in June, 2 in September, and 3 in October. No cases were admitted during the winter months. Age: The disease is most common in the 3d and 4th decades of life; the youngest of our patients was 16 years old and the oldest 48.

In the majority of cases the onset is sudden, with a chill, fever, and severe headache; in a smaller number of cases the onset is a gradual one. In most cases prostration and incapacity for work are marked. Constipation is a prominent feature. In 4 of the cases vomiting and abdominal pain were present. Epistaxis was observed in 2 cases. Cough was present in many of the cases, was usually dry and with no or very scanty expectoration. The tongue was frequently moist, coated with a white fur, only the edges being red. The pulse is rapid, and, while it does not vary according to the height of the temperature, it does not present the characteristic disproportion observed in typhoid fever. In our cases the pulse ranged during the height of the temperature between 90 and 120, and was frequently dicrotic. The blood-pressure was low in the largest number of cases, gradually rising after the temperature had reached normal figures. Eyes: The congestion of the conjunctiva was a prominent symptom in the largest percentage of our cases; in some cases a mucopurulent discharge was observed. The headache and prostration were the most prominent symptoms. The headache began with the onset of the disease, increased in severity, and did not abate until the temperature dropped to normal. This persistent headache, which did not subside with the progress of the disease, made it quite different from the headache of typhoid fever, which usually disappears at the end of the first week. Simultaneously with the headache prostration was very

marked; the patient complained of extreme weakness and appeared very ill. The patient lay listlessly in bed or moaned with his severe headache. The patient did not toss around as typhoid patients do because movement apparently increased his sufferings. Kernig's sign was present in most of the cases and the rigidity of the neck, in greater or less degree, was almost invariably observed. We were inclined to include this rigidity among the cardinal features of this disease. In one case the rigidity and retraction of the head were so marked, the headache so severe, and the tenderness along the spine so prominent that we decided to relieve the patient by making a lumbar puncture. Thirty c.c. of cerebrospinal fluid were obtained under high pressure; the fluid was clear with but few flocculi, gave a faint albumin ring, reduced Fehling's solution, and had 54 per cent. polynuclears and 46 per cent. lymphocytes. This fluid was examined bacteriologically with negative results.

The eruption is the most characteristic symptom of this disease. It usually appears on the 3d or 4th day after the onset, in one crop, and remains prominent during the febrile period, disappearing with the drop of the temperature. The spots are not roseolate, but rather of a maculopapular character. In size they are 2 to 4 mm. in diameter, sometimes discrete and very frequently confluent, resembling measles more than any other eruptive fever. The rash makes its appearance at once all over the trunk and extremities, rarely covering the face. Indeed, in none of our cases did we find any eruption on the face as recorded by other observers. The spots are slightly elevated and, as a rule, do not disappear on pressure. In severe cases the spots have a distinct petechial character. In some of our cases marked pigmentation of a pale yellow color was noticed after the eruption faded away. In the greatest number of cases the urine gave a negative diaze reaction on repeated examinations; only in three out of the 18 cases did we have a positive diazo reaction, but in no instance was it as strong as in a typical typhoid. The examination of urine and feces for bacilli of the typhoid group was negative in all of our cases. The blood count is characteristic. In none of our cases was there a leucopenia. The lowest number of leucocytes recorded was 7,400, the highest 17,800, the majority running between 10,000 and 12,000. Polynuclosis was marked in a few cases; in the majority of cases the differential count was normal. The Widal reaction was negative in every case on repeated examinations; in several cases these were made every second day. The agglutination test was made in several cases with the typhoid bacillus and also with other bacilli belonging to the typhoid group, namely the paratyphoid and colon bacilli. Blood cultures in all of our cases were sterile. The temperature curve is characteristic; following a chill it rises to 104-5° in twenty-four to forty-eight hours, and maintaining this level runs a subcontinuous course for ten, twelve, or fourteen days, when it falls by rapid lysis in from twenty-four to forty-eight hours. The temperature variations are not attended by corsponding changes in the pulse rate, though this is rarely higher than 90 to 120; it is nevertheless markedly higher than the characteristic slow pulse of typhoid. The respiration is slightly increased. The spleen is slightly palpable, and although moderately enlarged as evidenced by percussion, it never attains the size of the spleen in typhoid fever.

With this clinical picture in mind the question naturally arises, what is the essential nature of this disease? The answer to this question can be determined only by an insight into its pathology. Of the 221 cases reported by Brill there was not a single fatality, which left pathological investigation out of the question. Since Brill published his paper there was one death from this disease in his service, and the autopsy findings showed none of the characteristics of typhoid fever, although there were revealed certain degenerative changes in the various organs, chiefly in the hemopoetic system. Efforts to discover any possible relation either close or remote to typhoid fever showed by virture of negative agglutination tests, and absence of organisms in the blood and excreta, that this disease must be excluded from the typhoid group. It may be definitely concluded that this disease bears absolutely no relation to typhoid fever. But this does not warrant one in asserting that it is an entirely new clinical entity. For may it not be an atypical form of some disease other than typhoid? The only other disease to which it bears any close or superficial resemblance is typhus fever. We have had no opportunity of observing the latter disease in New York within the last two or threee decades. At any rate the symptomatic picture of Brill's disease tallies quite closely with the conception of typhus fever that some of us have had an opportunity of forming in our early medical career, either in this country or abroad. Typhus is endemic in Russia; and the fact that most of the cases of Brill's disease have been observed among Russian immigrants in this city may not be a mere fortuitous circumstance. In its sudden onset and its duration, with its petechial rash and cerebral symptoms, the resemblance to typhus as it is seen in Russia to-day is certainly striking. As an important opinion bearing upon this question I shall quote the statement of E. W. Goodall of the Eastern Hospital, Homerton, England: "To me the account given suggests typhus of a mild form; and further observations seem to be required before it can definitely be stated that Brill's disease is not typhus. A reference to Brill's own paper confirms this view. He writes, when discussing the diagnosis of the disease from typhus, as follows: 'In the case of an epidemic of typhus, in my opinion, it would be simply impossible to say that these cases which I have described were not mild typhus fever.' He appears to rely chiefly upon the non-epidemicity of the disease, its apparent want of infectiousness, and its mildness (there was not a fatal case amongst the 221 cases he has observed): the only clinical sign he notes as being different from typhus is the absence of the subcuticular mottling." Goodall further states that "Brill's cases were admitted to the Mount Sinai Hospital during the years 1896 to 1909. It is curious that of his last fifty patients (the details of which he tabulates as exemplary of the whole 221), thirty were Russians and twelve Austrians. In the sporadic cases of typhus I have observed of recent years in London most have been Russian Jews, who have not necessarily recently arrived in England. And, as regards the non-epidemicity and want of infectiousness, sporadic cases still occur in London which do not give rise to others even in what would seem to be the most favorable circumstances. But I admit that I have seen small groups of two or three cases in one family, and the disease may be fatal. Probably typhus in London is overlooked, because it is mild at present. I have twice found a case of the dis-

ease in a large general hospital in London, in which it was being treated as enteric. To me," concludes the London clinician, "Brill's paper proves that typhus fever in mild form still lingers in New York."

This opinion as to the contagiosity of this disease is thus directly at variance with that of Brill, who states that he has not observed a single instance of contagion in this condition. May not this failure be attributed to the attenuated character of the infection and the possibility that some of the cases, owing to their short duration, either do not come under the careful hospital observation or else are classified with typhoid fever? My own experience enables me to record one striking instance of contagion. One year ago I had an opportunity of observing three cases in one family presenting the typical picture of this entity. At that time, being unfamiliar with Dr. Brill's admirable description, I regarded these cases as typhus fever, and on this account I could not sanction their admission to my hospital service. The cases were those of two brothers and a brother-in-law living in one house, who took sick suddenly about the same time, with a high fever, hemorrhagic rash and intense headache, all characteristics of typhus fever. These cases were admitted to a county hospital and were discharged as cured after a typical course of two weeks' duration. In the light of my present knowledge I am not only inclined to include these cases in Brill's group but, furthermore, I would cite these as distinct evidence of the possible contagious nature of this disease.

To recapitulate: Brill's disease presents a typical temperature chart, a characteristic eruption, marked headache and prostration, presence of Kernig's sign and rigidity (or retraction) of the neck, and a totally negative pathology as to causative organisms or resultant lesions. If future investigation will show the non-identity of Brill's disease and typhus fever, one will be warranted in concluding that this handful of symptoms occurring together in no other recorded condition is a new addition to our nosology. The diagnosis is easily made if the above clinical picture is kept in mind, and, indeed, is rarely missed. Even our nurses are able to make the diagnosis. The prognosis is good, recovery taking place almost without exception. This is a very pleasing feature of this disease; it is certainly very gratifying to predict in any given case that the patient will get well in two weeks, will have no relapse and will be free from any of the dreaded complications following in the wake of typhoid fever. The treatment is entirely symptomatic, and no specific therapy is to be employed.

249 Hewes Street.

NOTE ON A CASE OF TUBERCULOUS MENINGITIS.*

WITH A REMARKABLE ANTE-MORTEM RISE OF TEMPERATURE.

By HOWARD D. KING, M.D.,

NEW ORLEANS, LA.

Tuberculous meningitis in adults presents so many difficulties of diagnosis and otherwise which are apt to lead one into error that I am prompted to recite my experience in a case recently coming under my observation. This type of meningitis in adults is likely to baffle the keenest clinical worker by reason of the variance of the symptoms present in the patient from those described in the standard texts. In no other conditions are the chances for erroneous diagnosis greater than in tuberculous meningitis, the reasons for which are many and varied. Tuberculous meningitis in adults is usually the finality of some other tuberculous process, in the majority of cases pulmonary tuberculosis. Debove[1] classifies the meningeal affections connected with phthisis as (a) meningeal tuberculosis; (b) granular tuberculous meningitis with inflammatory exudation; (c) tuberculous meningitis without the finding of the tubercle bacillus. If the lungs should prove the non-causative factor, a continuance of the search will probably bring to light eventually some hidden tuberculous focus. This focus may be located anywhere, in the lymphatics, mesentery, bone, etc.

The patient whose illness forms the basis of this paper was M. G., a female, 30 years old. Family history has but little bearing on the case, but I have reason to believe a brother died of phthisis, though denied by the family. Personal history of the patient is not of much value, as the family, for reasons known only to themselves, to a great extent concealed or distorted facts. The family, once in affluent circumstances, did not, I believe, resort to the concealment of the patient's antecedent troubles in order to hamper me in my work, but merely to shield the family name from adverse comment as to the presence of "insanity in the family." However, by dint of questioning and scattered bits of information, I was able to learn, on the whole, that the patient had been in poor health for three or four years preceding. Patient at no time was a robust child. Menstrual irregularities served to make her life distressing at these periods. She was of a high-strung, nervous temperament, and held aloof from all but immediate members of her family. On account of her shyness and marked aversion to coming into contact with strangers, she resigned her position in a dressmaking establishment and for the last two or three years remained at home, going out but little. Patient suffered from a most severe form of acne which was a source of great anguish and mortification to her, because of the facial disfigurement. For the acne, which, not unnaturally in her sex, she regarded as the source of her unhappiness, recourse was had to innumerable remedies, even vaccine therapy, but to no avail. She was ultrasensitive regarding her affliction and on being warned as to the dangers that might ensue from "picking the pimples" would go off into a corner and cry. About two years ago patient suffered from a spell of hysteria lasting from six to eight weeks. Recovery was slow and since that date patient has been in rather feeble health. This state of affairs continued for about two years and, while the condition was never entirely satisfactory, it was not such as to occasion any alarm in the minds of the family. She received no medical attention whatever during these two years.

The illness covered by this paper began on January 1, 1911. Upon a visit from the family physician it was declared to be a recurrence of the hysteria and similar to the attack of two years previous. Bromide therapy to the point of saturation and general treatment by "long distance" was the extent of the therapeutic endeavors in behalf of the sufferer. The long distance treatment was accomplished in this wise: Once or twice a week a

*Read before the Orleans Parish Medical Society, April 24, 1911.

sister of the patient would go to the physician with a recital of the doings of the week as it concerned the patient, and a prescription or two would be written covering the case until the next visit of the sister. After three or four weeks of this long distance treatment the physician became ill and scant attention was given to the patient until the date of my first visit, March 6, at 11 P. M. When I first saw patient she was in a deep coma and could not be roused. After making a cursory general examination and obtaining the meager history recited above I came to the conclusion that I had a cerebral condition to deal with. I was unable to make a positive diagnosis, however, and, in fact, was on the brink of diagnostic uncertainty as to whether it was a case of typhoid or a cerebral condition due to the absorption of intestinal toxins. The pupils were unequal; there was some rigidity of the neck and spine; and a not too well marked hemiplegic condition on the left side. The next two days brought but little change, though the comatose condition did not appear as deep; but the patient was still decidedly drowsy, stupid, and apathetic. Temperature during the three days did not go over 101.8° F.

At the end of this period it was evident that there was some meningeal trouble, and on the fourth day I gleaned from the family that the patient had lost considerable weight and was a sufferer from a most persistent cough and also had had influenza the previous December. These facts, coupled with the clinical phenomena, strengthened my diagnostic clue and I was convinced that the condition was none other than tuberculous meningitis. To avoid any doubt and not to be misled further, I enlisted the aid of a neurologist and after a thorough examination, including all the reflexes, we arrived at a tentative diagnosis of tuberculous meningitis. Babinski's sign was negative; Kernig's sign was present to a slight degree.

Lumbar puncture brought out the following facts: Twenty cubic centimeters of cerebrospinal fluid were removed at very high pressure, the examination disclosing a marked lymphocytosis. There was a fibrin clot well formed, though made up of delicate coagulæ; no tubercle bacilli were demonstrable. Noguchi's[2] globin test was positive. Fluid on removal was remarkably clear, but later became slightly turbid. The condition of the patient gradually grew worse and on the thirteenth day of her illness the patient was removed to the Presbyterian Hospital, as the resources of the family had become nearly exhausted. One might say that the diagnosis in this case was erroneous, but I will present in detail the obstacles which prevented at the outset a positive diagnosis. The meager history obtainable as to the antecedent troubles may be excluded, as the physician is presumed to make a diagnosis based upon his own observations. At first sight the patient presented a typical "third week typhoid" appearance, but this idea was speedily routed by the fact that the day of my first visit was the first time fever had manifested itself. Widal agglutination test the next day proved negative.

Throughout the entire illness the patient was weak and drowsy. Pressure over the lower limbs seemed to cause pain. The patient was obviously very ill, the tongue was thickly furred, cracked, and dry; the breath was fetid and the sordes were disgusting. The examination of the cerebrospinal fluid obtained by lumbar puncture according to Quincke[3] did not show the presence of tubercle bacilli. The ophthalmoscopical findings also proved negative. Therefore, the question of diagnosis rested entirely on the clinical symptoms and the cytological evidence as found in the cerebrospinal fluid. The fact that a marked lymphocytosis coincident with the clinical picture as herein presented was observed should be sufficient grounds for the making of a diagnosis of tuberculous meningitis. Notwithstanding this, one is forced to consider in the differential diagnosis of tuberculous meningitis a number of diseases presenting clinical pictures similar to that of tuberculous meningitis. These conditions are principally delirium tremens, hysteria, uremia, septicopyemia, typhoid fever, and head symptoms in certain dyscrasic states.

Ten days after withdrawal of spinal fluid a differential white count was made and the following result was obtained: Small lymphocytes 9 per cent., large lymphocytes 2 per cent., polymorphonuclear neutrophiles 88 per cent., transitional 1 per cent.; total white blood count, 12,222. In tuberculous meningitis an increase in the number of leucocytes, as a rule, is rare, but there are cases in the literature in which counts ranging from 14,000 to 34,000 have been recorded. The hyperleucocytosis in this case was due to a complicating terminal pneumonia. Thus it can be readily seen that the later findings did not invalidate the diagnostic import of the primary lymphocytosis. Wilson and Chowning[4] state that a hyperleucocytosis is usual in cases of so-called "spotted fever" of the Rocky Mountains, which is nothing more or less than cerebrospinal fever. As a rule, lymphocytes abound if the inflammatory process is tuberculous, while the polymorphonuclear type reigns in nontuberculous cases. Marcou-Mutzner[5] records a case in which the predominant cell was a polymorphonuclear leucocyte, despite the fact that necropsy showed a typical pulmonary and meningeal tuberculosis. The blood count in tuberculous meningitis has been found to differ in a marked degree from that obtained in other tubercular processes. The usual blood count in a slowly progressing tuberculous condition shows, as a rule, a leukopenia, while in tuberculous meningitis there is generally a demonstrable increase.

Oppenheim[6] in discussing the clinical picture of tuberculous meningitis as it occurs in adults says: "The early delirium and mental confusion which soon occur point out that grown-up patients may go about in this stage and appear mentally affected; sometimes they are in a dreamy state, sometimes excited and agitated, often to such a degree as to closely resemble persons under the influence of alcohol." Brown[7] is led to remark, "in certain instances there has been great difficulty in making the diagnosis from hysteria, early mental disease, or delirium tremens." Warrington[8] records a series of seven cases and makes the following observations: "When previous tubercular disease is not known and evidence of disease elsewhere can not be found the opening symptoms are very difficult to interpret." According to Bonney,[9] pulmonary disease apparently making satisfactory progress is often the forerunner of tuberculous meningitis.

The diagnosis of meningitis, as well as the special type of the infection, has recently acquired greater certainty by resorting to lumbar puncture. That this method of establishing a positive diagnosis is, in the great majority of cases, reliable and satisfactory is evident from the following table:

Name of Observer	Number of Cases	Tubercle Bacilli Found in Cerebrospinal Fluid
Hemenway[10]	137	135
Bernstein[11]	102	100
Park & Krumweide[12]	83	69
Dunn[13]	60	15
Norris[14]	50	47
Furbringer[15]	37	27
Schwarz[16]	22	16
Slawyk & Manicatide[16]	19	19
Warrington[8]	7	4
	517	432

Morse[17] says: "It is true, of course, that the cerebrospinal fluid in tuberculous meningitis contains tubercle bacilli. They are missed in about 90 per cent. of the cases, however, if the examination is the usual routine one." Osler[18] states: "A sterile fluid which is sometimes present also favors the diagnosis of tuberculous meningitis." In the differentiation of the type of meningeal inflammation the clearness of the fluid is regarded as a valuable means of distinguishing the tuberculous from the other forms. The demonstration of tubercle bacilli in the cerebrospinal fluid can not always be done, and their absence therein should not be regarded as sufficient evidence for a negative diagnosis. Dunn[13] says in speaking of the cytodiagnosis of tuberculous meningitis: "The main reliance is placed on the predominance of the mononuclear lymphocytes as shown by a different count of the cells in stained cover glass preparations. In the writer's analysis of sixty cases this predominance of lymphocytes was present in every case, and its absence should be regarded as precluding a diagnosis of tuberculous meningitis." Lucas[19], who has given a great deal of study to the cell findings in the spinal fluid, states that there are many conditions that give rise to the same cytologic findings in the spinal fluid: (a) Encephalitis, (b) epidemic myeloencephalitis, (c) meningismus, (d) tuberculous meningitis, and, (e) syphilis; secondly, that the presence of the mononuclear lymphocytes in the spinal fluid can not be the basis for a diagnosis of tuberculous meningitis; third, that the recovery from animal inoculation or the finding of the tubercle bacillus microscopically are the only positive means of making the diagnosis of tuberculous meningitis: fourth, that the study of the spinal fluid, although very important, must go hand in hand with more accurate clinical studies of such borderlying cases as are frequently confused with tuberculous meningitis. Thus, from the foregoing observations one can see that the only reliable method of establishing a diagnosis, the finding of the tubercle bacillus, is a much mooted question. Notwithstanding the researches of Lucas, a great many leading authorities attach much diagnostic significance to the occurrence of lymphocytosis.

Aside from the difficulty encountered in making a diagnosis the most interesting feature of the case was the accompanying temperature. The caprices exhibited by the temperature were puzzling and inexplicable. At times there would be distinct remissions, only to be followed by a spurt upward and then a sudden downward plunge. Often the temperature oscillations were as much as 2° within as many hours; one morning the temperature would be very high, and the evening temperature low. The next day conditions would be entirely reversed. The day following the withdrawal of the spinal fluid the temperature dropped nearly to normal, only to rise very high the next day. The pulse was not always commensurate with the febrile reaction. On the fourteenth day of illness, the date of patient's removal from home to the hospital, the temperature began to maintain a more definite course, and the ascensions and declinations were not as freaky. The temperature on the fifteenth day of illness reached 105.2° F. with a pulse of 100 and respiration 46. Within the next two hours there was a decline of 2°, though the pulse rate was increased to 128 and respiration had dropped to 36. For five hours temperature 103° F., pulse 128, and respiration 36 remained unchanged and then within the short interval of three hours the temperature leaped to 106.5° F., pulse 140, respiration 48. This sudden change was noted at 6 A.M. and three hours later temperature was 107° F., pulse 145, respiration 60. From this hour the temperature kept mounting higher. To avoid the chances of error in observation several thermometers were used, all with the same result. At 1 P.M. the temperature was 107.8° F., pulse 170, respiration 76 and at 5 P.M. the temperature had reached 110.8° F. Forty minutes after this was recorded the patient expired. A terminal pneumonia hastened the end.

As a rule in tuberculous meningitis just before dissolution the temperature sinks to 94° or 95° F., though there may be a hyperpyrexia. Osler[18] calls attention to a case of Baumler in which the temperature rose just before death to 110.7° F. It is the expressed opinion, though the comment is a rather grim one, that the infallibility of the diagnosis is best established by the death of the patient. That there are exceptions, however rare, to this dictum is acknowledged by a few leading authorities. Some observers doubt the invariable fatality ascribed to the disease and cite certain well authenticated recoveries. Goliski in his clinic in Vienna was in the habit of displaying the brain of a child in which tuberculous meningitis had been the diagnosis. The old scars (healed) at the base of the brain were demonstrable. This case is of interest, as the child succumbed to an entirely different disease some time after. Martin[20] says recoveries are possibly more frequent than has been believed and states that since 1894 there have been no fewer than twenty full recoveries. There are some cases that seemingly recover completely only to be taken ill again in a short time. Allaria[21] classifies the foregoing type as an intermittent form in which the tuberculous process develops at intervals. During the abatement of the condition the patient is to all appearances well. In these cases resistance is so much above par that the infection is checked in its incipiency or the bacillary virulence is decreased to such an extent that the meningeal lesion becomes localized and subsequently undergoes fibrous metamorphosis. These supposedly latent lesions at a later date form the focus of a fresh infection which always terminates fatally. It is in these cases that the prognosis must be carefully weighed.

Summary and Conclusions.—The diagnosis of tuberculous meningitis was based on the following facts: (1) Previous personal history of poor health and enfeebled constitution. (2) The illness, influenza, preceding the general collapse which rendered patient a fertile soil for tuberculous infection. (3) The evidence of pulmonary involvement, persistent cough, great loss of weight, and other physical signs. (4) The meningeal manifestations, cervical rigidity, Kernig's sign, and other clinical phenomena

peculiar to meningitis. (5) The cytodiagnostic evidence as revealed by examination of the cerebrospinal fluid, the amount and clearness of the fluid, the high pressure at which it was obtained, the delicate though firmly coagulated fibrin clot, and the marked lymphocytosis. (6) The death of the patient. Much to my distress permission for an autopsy was refused. After carefully weighing all the facts in the case I believe a "Scotch verdict" would not be inappropriate; and that, while it was not proven absolutely to be a case of tuberculous meningitis, it was not proven otherwise.

A CASE OF MISSED ABORTION.

By J. OHLBAUM, M.D.,

NEW YORK,

The following case is of sufficient interest in my opinion to place on record.

Mrs. L., age 36, Russian, married eighteen years, mother of three living children, oldest fifteen years, youngest three years old. First pregnancy was instrumental delivery and child died immediately after accouchement; one miscarriage.

Present history: Last menstrual flow occurred in May, 1910. In June, 1910, the woman began to show her usual early symptoms of pregnancy, *i.e.* cessation of menses, which had been punctual outside of her puerperal periods, morning sickness, and the enlargement of the breasts. She consulted several physicians when her menses ceased and was told she had a pregnancy of three months or thereabouts. At about the fifth month from the time her menses ceased she commenced to look for signs of "life," which did not appear. She went the rounds of the different clinics in the city, and finally she diagnosed her own case as one of early menopause and ceased to give herself a thought about her condition. She was gaining in weight and felt comfortable.

On March 12, 1911, at about 3 A. M. she commenced to have cramp-like pains and thought they were from her bowels, having eaten some food the night previous which might have caused her to have a "spoiled stomach" as she called it. The pains became more severe and she decided to send for a physician. I was called in and reached her home at 7.30 A. M. March 12. When I got there I was shown a sac which she had expelled. On examination I found it contained a fetus of about three and a half months. The fetus, cord, and placenta were all connected. Microscopically the placenta showed a fatty degeneration of the entire mass. The fetus was of a dirty, dark, brownish black appearance.

The interesting point of record is that this woman had been carrying a dead fetus *in utero* for probably six and a half months, without it causing her to have any physical disturbance whatsoever.

1665 Lexington Avenue.

Familial Cretinism in Vienna.—R. Eller reports three cases of cretinism occurring in children in one family in a locality free from endemic cretinism. He notes that the symptoms of endemic and those of sporadic cretinism cannot be distinguished from one another.—*Jahrbuch für Kinderheilkunde.*

Value of Examination for Acetone in Gynecological Surgery.—O. Paleani has made examinations of the urine in several cases of internal hemorrhage, for acetone, with a view to ascertaining the value of the test in diagnosis of gynecological cases, which has been maintained by some authors. In the cases tested by him it was found that in spite of there being present in the abdomen large amounts of blood the test was not positive during the time previous to operation. In one old case the test was positive, however. In some other gynecological cases in which there was no blood in the abdomen the test was found to be absent. The obvious conclusion from the author's cases is that the presence of acetone in the urine of gynecological cases has no bearing on the diagnosis of internal hemorrhage.—*Il Policlinico.*

Deviations of the Knee in White Swelling of the Knee.—C. Ducroquet and Victor Veru state that in clinics for orthopedics one is struck by the frequency of the deviations of the knee due to tuberculosis. This deviation is at first pure flexion, and this will remain indefinitely if the child does not walk. Later we see a complex angular deviation consisting of moderate flexion, abduction of the leg, and outward rotation of the foot. This is produced by walking, occurring early in patients who are badly immobilized, and late in those who have not complete ankylosis. The results are the same in both conditions, as manifested in the limitation of motion. The position is assumed by the patient of lessening the length of the limb, which cannot be entirely flexed in bringing the leg forward. Flexion of the knee is indispensable for normal walking. The patient rotates the leg forward, which produces this peculiar deformity. To prevent this deformity all that is necessary is a proper apparatus to prevent motion at the knee, and which shall extend above to the ischium and great trochanter, and below include the heel and back part of the foot. There should be rest in bed for six months, then walking with a proper apparatus, which must be worn for another year. Then an articulated apparatus should be worn until the child has perfect motion. If this is not attained and a perfect ankylosis occurs with slight shortening or flexion walking is good with a slight limp. If flexion is less than ten degrees the apparatus should still be worn until flexion improves. If this does not occur he must walk in external rotation and deformity will certainly occur. A resection is to be recommended.—*Archives de Médecine des Enfants.*

INDUSTRIAL ACCIDENTS AND COMPENSATION FOR THEM.

ONE of the live questions before the country to-day is that of workmen's compensation for industrial accidents. The decision of the New York State Court of Appeals declaring unconstitutional the law recently enacted fixing the rate of compensation for which employers were liable to their injured employees, a decision which was based on the constitutional provision that no one can be deprived of property without due process of law, places this subject in the limelight of public attention. There are few questions that have interested such a large group of individuals, including, besides the vast army of industrial workers, publicists, physicians, jurists, legislators, lawyers, sociologists, and employers. The fundamental constitutional question involved, interpreted in the manner that it has been by one of the most influential courts in the country, threatens to undermine all legislation that has been enacted in the various States fixing workmen's compensation. The probability is that future legislation along this line will be possible only in the event of amendment of both the national and the State constitutions.

In a most illuminating essay upon the various humanitarian, economic, and legal aspects of this subject, Mr. Gilbert L. Campbell* quotes the report by the New York Commission on the question of employers' liability as follows: "The hazardous employments of the State annually exact their toll of life and limb of the workers with astounding certainty; . . . . there is a mathematical ratio of industrial accidents in the hazardous trades, depending upon the speed at which industry moves and upon the number of workmen, as remorseless and as certain as the death rate on which the tables for life insurance are based."

It is the truth of this statement that brings into sharp relief the fallacy, when applied to modern conditions, of the old doctrines of the common law that have been applied in England and in this country in the determination of employers' liability, namely, the doctrine of contributory negligence, the doctrine of assumed risk, and the doctrine of the fellow-servant. In the doctrine of contributory negligence it was long ago enunciated that if the plaintiff had so contributed to the causes of the accident that the breach of duty on the part of the defendant was not its proximate cause, then he, the plaintiff, had no ground for action. In the doctrine of assumed risk it was declared that he who knowingly places himself in danger of personal injury by accepting hazardous employment assumes therewith the risk of injury. The fellow-servant doctrine, which was not enunciated until 1837, asserted that danger of injury through the negligence of another servant of the same master is a known, common, and ever-present risk of working in company with others, and that consequently a worker so injured has no ground for action against his employer. Campbell states that, although the common law affecting the liability of the employer has been greatly modified by statutory enactments in many States, the judge-made laws concerning negligence, assumed risks, and the fellow-servant are still dominant. But the conditions of to-day in the industrial world are not the same as those that prevailed when these legal maxims were enunciated. "Modern creative processes have brought multitudes of workers into direct contact with ponderous implements of production that render their occupations extremely dangerous and have also made expedient, if not necessary, complicated relations between owners, managers, superintendents, foremen, and employees. In these modern industrial organizations the common worker may be far removed from fellow employees and employer, and thus his individual importance and responsibility are often reduced to a minimum. . . . . The common law of liability, an outgrowth of the past, is no longer in harmony with the social organism it aims to serve, while statutory modifications in many States have been inadequate to remedy its deficiencies."

It is pointed out that in the modern method of human slaughter America takes the lead. While producing one-third more coal per mine-worker than does Europe, it kills and cripples three times as many men. The psychological weakness which makes workmen who constantly face danger grow careless of it, the mechanical imperfections which no care can eliminate, and natural phenomena that cannot be foretold, all tend to make inevitable the loss of many lives by accident. These lives are sacrificed, therefore, as a necessary cost of production. But it is asked, "Who bears the cost? Is this loss met by the profits of production, or does it fall upon individual workers?" It is unfortunate that in most instances under the present system this loss falls upon the workers.

The hardships of the victims of industrial accidents have been met in various ways: By the crude and paltry benefits granted by the workmen's own mutual organizations; by the voluntary payments of kind-hearted employers, only too few; by the establishment in large industrial organizations of relief departments, with a graded scale of benefits, in which the company bears either part of or the entire expense of compensating its employees or their dependents; and by accident insurance, either individual or collective. None of these is regarded as an adequate mode of relief. Even if every employee insured himself against accident, or if the employer insured his employees collectively, the

*"Industrial Accidents and Their Compensation." Boston and New York: Houghton Mifflin Company, 1911.

total losses paid would constitute only about 46 per cent. of the premiums, as shown by the figures of the liability companies for the five-year period ending with 1908. During the latter year twenty-seven leading casualty companies collected $47,098,549 in premiums. Of this sum 45.7 per cent. was paid for losses, 50.01 per cent. for expenses, and but 4.2 per cent. remained as the net underwriting profit in the business. These figures show, as do those for other forms of insurance, that the business is not unduly profitable. Yet the system that returns to the victims of accidents less than one-half of what had been contributed in premiums is open to objection.

What, then, are the remedies for the prevailing inadequate measures of distributing the losses from accident involved in the complex machinery of the modern industrial organization? Drawing his conclusions in part from "Trades Unionism and Labor Problems," by Professor John R. Commons, Campbell suggests the following program of reform: Employers should be held accountable for the safety of surroundings and equipment and for the negligent acts of their employees. The employer's defense of contributory negligence should be denied. Employers should be held accountable for unpreventable accidents. They should bear the burden of proof. Compensation should be paid according to a definite scale fixed by law and varying according to the age and pecuniary condition of the dependents. Payment should be guaranteed by adequate insurance. Compensation payment should be conserved. Courts of proper jurisdiction should be given authority to determine whether lump payments should be made or the sum invested in annuities.

Campbell concludes his admirable contribution to this subject in the following words: "The situation presents a problem in the equitable distribution of the fruits of industry. Production commands a sufficient economic return to meet all of its legitimate charges, and a reasonable portion should be turned to the account of those unfortunates whom industrial accidents leave without means of livelihood. The costs fall with crushing force upon the individual victims. If these costs were to fall upon the enormous capital and tremendous earning power of the industrial world they would seem insignificant. Yet absurd legal precedents set up generations ago, and now dishonored at their source, are effective barriers against proper distribution. Legislation that pulls down these barriers will add much to the security, contentment, and efficiency of American industry."

THE PURIFICATION OF SEWAGE AT ITS SOURCE.

Typhoid fever on this continent is one of the most deadly diseases. The Professor of Hygiene at McGill University stated recently that almost all the public water supplies of Canada were polluted or in the process of being polluted. Considering the immense area of Canada and its comparatively sparse population this is a severe arraignment. However, the United States, or, rather, its sanitarians cannot plume themselves on any marked superiority in this respect over the neighboring dominion. Despite the progress made in purifying public water supplies and consequently in preventing typhoid fever, our country compares unfavorably with some countries of Europe. In Great Britain and Germany, for instance, under more inauspicious conditions by far, typhoid fever has been nearly abolished. In America, generally, the disease has been scotched only.

Bayard Holmes of Chicago writes in the *American Journal of Clinical Medicine* for August, 1911, regarding the septic tank as a practical means for preventing typhoid fever. By this is not meant the septic treatment of sewerage on a large scale in connection with a filtration plant, but the use of septic tanks for the treatment of household sewerage. Many persons will possibly imagine that such a scheme is not practical, but according to Holmes it is not only eminently practical but more or less easy of design and construction, and on the whole, too, the most efficient. Holmes computes the ordinary sewerage from a household of five people at 1,500 grams (50 ounces) of fecal matter, 5,000 c.c. (10 to 11 pints) of urine, and 100 gallons, more or less, of water containing precipitated soap from the bath and much grease and detritus from the kitchen sink. The grease, which is the least perishable, must be dealt with separately. As for the rest of the sewerage, which is perishable and contains within itself all the elements necessary for its own destruction and purification, treatment in the septic tank is indicated.

"This portion of the sewerage should be conducted into a water-tight fermentation tank, which should hold about twice more than the maximum daily output from the household. It should not be more than one hundred feet distant from the house and connected with it by hermetically sealed pipes of glazed tile or iron. The catch-basin, the fermentation tank, and these pipes should be kept freely open to the air by vents running above the roof or the surface of the ground. The septic tank and all drains should be below the post-line and wholly unconnected with gutters from the roof or any other irregular flooding. Another distinct system should take care of the storm water." Holmes proceeds to sketch the complete system of the domestic septic tank and states that when the sewage flows out of this tank it is slightly turbid water of a specific gravity less than that of urine. It is almost without odor, and it contains few if any living pathogenic microorganisms. It can be discharged into an open ditch without producing offensive results, and can be collected into a pond which remains perfectly clear summer and winter. If discharged into a small brook it will not kill the fish nor pollute the stream. It may be discharged into drainage tiles without befouling them, or it may be discharged into sandy soil by letting the end of the outlet pipe open under ground into a hole filled with stone or coarse gravel. It is urged that while one such tank may be constructed for each house, the better plan would be one for each block, with a single outlet into the sewer in the street. It is argued that not only the problem of preventing hookworm disease and typhoid fever can be solved by the use of a modified

and simplified septic tank, but that the nuisance and danger of flies migrating from the privy outhouse to kitchen and *vice versa* can be obviated?

If the methods sketched by Holmes are feasible, and from the description they read as if they might be, the contention that their universal adoption would effectually prevent typhoid fever and hookworm disease is based on sound premises. Typhoid fever would be attacked at the source and cities would be spared the expense of installing elaborate and expensive sewage purification plants, and perhaps filtration plants. Of course, it is too much to hope that the plan will be at once, if ever, generally employed, but its employment even on a small scale would be a step in the right direction. In country districts, if effective, the scheme should work wonders. So long as open privies are in general use in rural districts, and so long as the sewage of cities is dumped into the nearest body of water without being sterilized in any way, just so long will typhoid fever levy its heavy death and sickness toll on the careless inhabitants of this continent.

NEW METHODS FOR THE DIAGNOSIS OF MALIGNANT DISEASE.

No better idea of the practical advances along biochemical lines is procurable than that which is concerned with some individual problem, such as the diagnosis of malignancy. Hirschberg of the Cancer Research Institute, Berlin, has been summarizing these methods in a series of articles in the *Deutsche medizinische Wochenschrift* (Nos. 27, 28, 29). He begins with chemical tests which are divided into urinary, blood, and gastric-juice reactions, the latter pertaining only to cancer of the stomach. The urine tests are not concrete, and deal chiefly with the fluctuations of the urinary ingredients in malignancy, nothing conclusive being obtained thus far from this line of research. The blood tests comprise at least one concrete reaction, to wit, the elevation of the antitryptic index. There is no doubt that the index is greatly increased in cancer, but not alone in that affection. It may therefore be of use when certain other affections can be excluded. The literature of this subject is large and increasing. There are a number of tests of the gastric juice for gastric cancer which may be passed over since they are not applicable to cancer in general.

Morphological studies of the blood deal with alterations in the blood count and do not lead to the isolation of specific tests. Of much greater significance than any of the preceding are the serological tests, for here we have a right to expect specific reactions if such exist anywhere. In regard to the existence of complement fixation authorities are divided in opinion. It is certain that results are usually negative when they should be positive. On the other hand some positive reactions are to be attributed to latent syphilis, etc.

The same inconstancy applies to anaphylactic reactions. In regard to the demonstration of isolysins, hemolysins, heterolysins, cytolysins, and precipitins, all of these bodies have been found, and when present they are of possible value in the detection of latent cancer. For example, Freund's cytolytic reaction in a person formerly subjected to cancer removal is held by some surgeons to be of much value (solution of cancer cells by serum of cancer-free individuals). Kelling's heterolysin test is held to be practicable in two-thirds of all cases. Last, but not least in bulk of literature, is the miostagmin reaction, which is of course not specific for malignancy, being much used in tuberculosis. It appears to be of only conditional value in cancer. In his final summary Hirschberg is somewhat pessimistic as to results actually accomplished, but thinks that in the future the enormous labors performed to date will not have been in vain.

OCCUPATIONAL TREATMENT OF INSANITY.

Writing in the *Monthly Cyclopedia and Medical Bulletin* for May, 1911, Frank Wade Robertson urges the value of occupation for mind and body in the treatment of various psychoses. He says that in studying old-time methods of treating the insane one is impressed with the dependence placed upon drugs and the ceaseless search for a specific for each and every form of mental disease, and he notes that it has been only tardily discovered that no therapeutic panacea is available in the treatment of insanity. He draws attention to the fact that in 1845 Earle showed how much good was to be derived from the employment of manual labor in the treatment of the insane. Bell in 1838 wrote that he attributed his success in the treatment of the insane very largely to "systematic, regular employment in useful bodily labor" and to the amusements provided. It has been the experience of Robertson in the treatment of the psychoneuroses where the power of attention has not been too much disturbed, that well-selected amusements, card-playing, games, plays, and conversation upon subjects which arouse the patient's interest frequently have a beneficial effect.

As a means of both exercise and occupation, the crying need of our hospitals and sanatoria to-day, Robertson insists, is for properly equipped workshops and amusement rooms for men and women. The effect on the patients would be twofold; exercise and occupation would benefit body and mind, and the disciplinary effect on the patient would act as a curative measure of inestimable value. Thus, in the opinion of the writer, in place of the aimless inactivity which at present characterizes many of the abodes of the insane, there would be animation, activity, and enthusiasm among the inmates.

The good results of occupation in the treatment of the insane were also emphasized by Dr. Mary Lawson Neff in an article published in the Medical Record, December 3, 1910. In this the author referred to the fact that work, especially basket-making, was insisted upon in the York Retreat as early as the latter part of the 18th century, and she showed how games could be made use of, as well as industrial occupation, in psychotherapy. From all points of view, healthful occupation would exert a favorable influence on those suffering from mental disorders of different kinds and of varying stages of intensity. The curative value of trade schools

has already been partially demonstrated in the treatment of defectives and there would seem to be cause to anticipate an equally favorable outcome from the application of similar methods of treatment for the insane.

Tolerance of Nurslings Toward Morphine.

Many therapeutists insist that opiates must never be given to infants during the first year of life, and much has been written against the use of "soothing syrups" during this period. It has been alleged that many babies go through their colic and teething ages in a state of virtual stupor, and despite all this propaganda it is known that most mothers make some use of opiates, or at least did so before recent restrictive laws went into operation. Every physician in family practice must have heard of families of intelligence and cultivation who threw out accumulated empty bottles of soothing syrup literally in basketfuls. Nevertheless, the number of actual cases in which responsibility for death can be traced directly to paregoric and soothing syrups, even if considerable, must be relatively small. Now, while everything which has been done in warning against the use of opiates in the first year of life, and, in fact, at any other period, is wholly admirable from any point of view, the fact undoubtedly remains that nurslings are really very tolerant toward these drugs. It would be better to state perhaps that some infants exhibit this tolerance, for we cannot assume that the reverse does not occur. When cases occur such as that reported by Wichura in the *Münchener medizinische Wochenschrift* of July 25, in which recovery readily followed poisoning of an infant three months old with at least a twentyfold dose (for the first-year period) of morphine, we cannot always attribute this resistance to idiosyncrasy. A similar tolerance to codeine has also been noted. The truth of the matter is doubtless that a nursling may readily show the effects of morphine—the pupils and sensorium may rapidly respond to minute doses —but that the lethal dose is much larger than has hitherto been taught. The bearing of the subject is principally forensic in character, for practically the fact remains that opiates should never be used in domestic practice for either infants or adults, and should be prescribed for infants by the physician with caution and only when definitely indicated.

Cadaveric Rigidity.

The older teaching as to the nature of cadaveric rigidity was very simple and plain. It was due solely to coagulation of the fluid muscle albumin, and analogous to coagulation of blood fibrin. At a recent session of the K. K. Gesellschaft für Aerzte (*Münchener medizinische Wochenschrift*, July 18) von Fuerth and Lenck announce as a result of years of experience that this theory is best replaced by another. According to these investigators the acid formed in the muscle after death causes the muscle fibers to swell up, becoming thereby shorter and thicker. This causes the rigidity proper. The following coagulation of the muscle albumin represents the relaxation which follows on rigidity. If measures are employed which tend to promote this coagulation the latter is hastened. Thus this occurs if muscle is placed in the incubator. Violent muscular exertion shortly before death hastens the onset of rigor mortis because of increase in the amount of sarcolactic acid. On the other hand, the presence of oxygen prevents rigor mortis because it hinders the formation of sarcolactic acid. If the muscle is infiltrated with Ringer's solution the commencing rigidity is made to retrograde because the acid is washed out. There are *in vitro* a type of rigor mortis due to heat and another due to drugs (quinine and chloroform).

News of the Week.

Industrial Poisonings to be Reported.—An amendment of the labor law of New York State, passed by the Legislature on June 6, reads as follows: "1. Every medical practitioner attending on or called in to visit a patient whom he believes to be suffering from poisoning from lead, phosphorus, arsenic or mercury or their compounds, or from anthrax, or from compressed air illness, contracted as the result of the nature of the patient's employment, shall send to the Commissioner of Labor a notice stating the name and full postal address and place of employment of the patient and the disease from which, in the opinion of the medical practitioner, the patient is suffering, with such other and further information as may be required by the said commissioner. 2. If any medical practitioner, when required by this section to send a notice, fails forthwith to send the same, he shall be liable to a fine not exceeding ten dollars. 3. It shall be the duty of the Commissioner of Labor to enforce the provisions of this section, and he may call upon the State and local boards of health for assistance." This act will take effect on September 1.

A Plan for Better Vital Statistics.—The Monthly Bulletin of the New York Department of Health for July discussed the report of a committee appointed some time since to consider the relations between public health and vital statistics, as the present system is considered quite inadequate. This report, after enumerating the benefits that would accrue from more carefully and accurately kept statistics, recommends that the city be divided for purposes of tabulation into small sanitary districts which should coincide wherever possible with those of the Census Bureau; that deaths, births, and marriages for the year 1910, and for subsequent years, should be tabulated by these tracts; that there should be a working agreement with the Census Bureau to avoid reduplication of work; that an estimate should be made of the cost of producing statistical tables now published, and the possibility of changing the tables so as to secure better results for the same money considered; that in selecting subjects for statistical investigation emphasis be placed on those in regard to which the public is interested or can easily be aroused, and upon which other divisions of the Department of Health are working; that the State enumeration of 1915 be taken with reference to its serving as a basis for the vital statistics of New York Ciy. The committee further suggests that the name of the present Bureau of Records be changed to the Bureau of Vital Statistics, and that it be reorganized under three divisions, namely: (a) Division of records; (b) division of research; (c) division of publicity. Each division shall have its own chief, who shall receive $5,000 a year. The members of this committee are Prof. Walter F. Wilcox of Cornell University; President C. A. E. Winslow of the College of the City of New York; Dr. Cressy C. Wilbur.

Dr. Robert S. Tracy, Dr. William H. Guilfoy, Dr. Herman M. Biggs, and Dr. Josephine S. Baker, director of the Department of Child Hygiene.

For a Children's Bureau.—A bill to establish a children's bureau in the Department of Commerce and Labor has been reported favorably from the Senate Committee on Education and Labor. The bill requires that the commissioner of the new bureau shall gather information on all subjects relating to child life, accidents, mortality, and dangerous employments, as well as to child delinquents and juvenile courts.

Salt Lake City Uses Typhoid Vaccine.—The apparent efficacy of vaccination for typhoid fever has led the Salt Lake Board of Health to begin an active campaign for its use in putting an end to the ravages of typhoid fever The board has not yet decided to make the use of the vaccine compulsory, but that it will constantly have the preparation on hand and that city physicians will administer it free of cost.

New Milk Station Opened.—The Board of Health of New York City announces the opening of a pure milk station in Division street. This is the fifteenth station to be opened by the department.

Infant Death Rate.—The total number of infant deaths in New York City from January 1 to August 12 was 9,398, as compared with 10,365 for the same period in 1910, a total decrease of 967. It is the hope of the Health Commissioner to show a difference of 1,000 by the end of the summer. For the week ending August 12 there were 410 deaths of infants under one year of age, and for the corresponding week of 1910, 422. The week ending August 19 shows 412 deaths of infants under one year of age, as against 396 for the corresponding week of 1910.

Summer Work at Sea Breeze.—Up to August 15 the Association for Improving the Condition of the Poor has sent 17,059 mothers and children to Sea Breeze, Coney Island, while, for the entire summer of 1910, 25,886 mothers and infants were given outings.

Typhoid Fever and Poliomyelitis.—In New York City there have been 576 cases of typhoid fever reported to the Health Department in the last ten weeks, as compared with about 300 for the corresponding time in 1910. In July 318 cases of typhoid fever were reported for the greater city and 56 deaths. For the first twelve days of August there were 279 cases reported, as against 191 in 1910. The greatest number of cases in Manhattan have developed in an area between 26th and 100th streets. Since August 1, 16 cases of infantile paralysis were reported to the Health Department, while not a single case was reported during the same time last year.

Ban on Public Drinking Cups.—The new sanitary code ordinance which will take effect in New York City October 1, 1911, abolishes drinking cups in hotels, public schools, railroad stations, factories, theaters, and all public places. Children will have to provide their own drinking cups at school, and those working in factories will have to do the same; it will be a violation of the law for any person to loan his or her drinking cup.

To Enforce Cold Storage Law.—The State Department of Health has been inspecting cold storage plants, especially in New York, Albany, Utica, Syracuse, Rochester, and Buffalo, and has demonstrated that there is great need for rigid enforcement of the law from the public health standpoint. The department will insist vigorously on the labeling of the food products as to date, receipt and delivery and also the selling of cold storage foods as such, and will prosecute those who have flagrantly violated the law.

Work of the Kitchen Association.—This society which has been assisting the Health Department in the campaign to save the lives of babies has at present more than 1,500 infants under its care and supports nine milk stations. It is said that there has been practically no mortality among the infants under its care.

Professor Albrecht Lossel, Director of the Physiological Institute of the University of Heidelberg, arrived in this country on August 12, and will deliver lectures at the Johns Hopkins and other American universities.

Dr. Amos T. Baker, Assistant Superintendent of the Matteawan State Hospital for the Criminal Insane, has tendered his resignation to take effect immediately, and will hereafter be connected with Dr. Flavius Packer's private sanatorium at Riverdale, N. Y.

Dr. J. L. Eaves, until recently pathologist to the University of Edinburgh, Scotland, has become a member of the Stamford faculty at the Cooper Medical College.

Hospital for Los Angeles.—The Frances Willard Hospital Association is preparing plans for a hospital building to be erected at Washington and Figueroa streets at a cost of $100,000.

Milk Exhibit.—At the State fair to be held in Syracuse in September the New York Milk Committee and the New York Dairy Demonstration Company will give a joint exhibit which will show methods of producing pure milk for New York at a nominal cost. The Milk Committee will show by charts and literature what is being done all over the United States in establishing uniform milk inspections, the proper relation between municipal and State authorities, and the need of inter-state cooperation. There will also be a reproduction of a city milk station with clinics by doctors and lessons by nurses. Charts, tables, and photographs will show what is being done in other cities to reduce infant mortality.

For Duty-free Lemons.—An effort is being made to enlist the hospitals in the campaign for the abolition of the duty on lemons. A circular has been sent to the superintendent of every hospital in the country, asking him to write to the Senators from his State to request them to vote for the reduction or abolition of the duty on this fruit, on the ground that a considerable reduction would thereby result in the working expenses of the hospital.

Hospitals and the Proposed New Charter.—One of the clauses of the proposed new charter for New York City provides for the transfer of Bellevue and the Allied Hospitals from the present trustee system to a commission to be appointed by the Mayor. At a recent hearing before the joint legislative committee, the United Hebrew Charities, the Society for Improving the Conditions of the Poor, and other philanthropic organizations protested against this change which would again make the hospitals the toy of the politicians. Leopold Plaut, the head of the Hebrew Charities, urges that all who are interested in the hospitals and the welfare of the sick poor use their influence with the Legislature to prevent this change.

Typhoid Epidemic at Canastota.—This village

with a population of 3,200 has at present 60 cases of typhoid fever. The water supply is said to be responsible for the epidemic.

Recent Cholera News.—The official report of the Italian Government shows that from August 8 to 12 there were 1,736 cases of cholera and 632 deaths in Italy. Since the last of July there have been 40 cases in Rome while during the previous six months there were only 13 cases. A dispatch from the Paris *Midi* states that there have been 37 cases of cholera at Marseilles and 20 deaths and that 60 soldiers at the Marseilles garrison are held in the hospital as suspected cholera patients. The report comes from Canada that 37 cholera suspects and 283 smallpox suspects are being held at the Dominion Government quarantine station at Grosse Isle. The *Re d'Italia* from Naples and Palermo, which arrived in New York Harbor on August 19, reported that three deaths of children from cholera had occured during the voyage and two passengers were suspected of having the disease.

Harvard to Have a Medical School in China.—That Harvard will have a medical school in Shanghia, China, within eight months seems an assured fact. Plans have been under consideration for about three years, and Dr. Martin R. Edwards has just returned from a seven months' stay in China, where he was sent for the purpose of studying conditions to determine in what place in China it would be best to start a medical school. There is a dire need of such an institution in China, there being at present but one fairly well trained physician to every 400,000 population. Two-fifths of the sum of money necessary for this project have been contributed by the Legislatures of Oregon, Washington, and California, these States being particularly interested in preventing the coming of cholera, bubonic plague, and other Oriental diseases to Pacific ports.

Dr. Percy Bartlett, of the Dartmouth College Medical School has been chosen to succeed Dr. Charles F. Richardson as trustee of the Mary Hitchcock Memorial Hospital at Hanover, N. H.

Dr. Alfred Mitchell, professor of the Theory and Practcice of Medicine and Dean of the Medical School of Maine, a part of Bowdoin College, since 1897, has resigned. Dr. Frederick H. Gerrish, who has been connected with this institution since 1872, has also resigned and has been appointed Professor Emeritus of Surgery and Professor of Medical Ethics.

New Dispensary for Medical College.—The regular physicians of Maine and the alumni of the Medical School of Maine have instructed the Trustees of Bowdoin College to raise $140,000 for building a dispensary and for laboratories of anatomy, physiology, bacteriology, pathology, and pharmacology.

Bathing in Flushing Bay Forbidden.—The Board of Health has closed the bathhouses on Flushing Bay, not because of the unsanitary condition of the bay, as was rumored, but because there were not sterilizing plants for bathing suits and there were complaints that this had led to the communication of disease.

A New Health Ordinance for Cincinnati.—The Health Department of this city has passed an ordinance requiring factory owners to place cuspidors on the floors of their establishments.

Hospital Changes Hands.—The Lutheran Hospital of Granite City, Mo., has been sold to Father Kaenders, who will put the institution in charge of the Sisters of Charity.

The Colorado State Board of Heath.—Dr. Arnold Stedman of Denver, Dr. James R. Arneil of Denver, and Dr. Charles Morrison of Colorado City have been appointed to vacancies on the State Board of Health of Colorado.

Benefit for Hospital.—A benefit for the Hospital of Milford, Mass., netted that institution $828.

Arkansas Medical Schools Unite.—The College of Physicians and Surgeons and the University of Arkansas Medical Department, both of Little Rock, have joined forces and will be controlled and financed by the University of Arkansas.

American Electro-Therapeutic Association.—The twenty-first annual convention of this American Electro-Therapeutic Association will be held at the building of the College of Physicians, Philadelphia, Tuesday, Wednesday, and Thursday, September 5, 6, and 7, 1911, under the presidency of Dr. Frederick de Kraft of New York. The secretary is Dr. J. Willard Travell, 27 East Eleventh street, New York City.

Obituary Notes.—Dr Herman P. Bender of Williamsburg, N. Y., a graduate of the University of Freiburg in 1879, was struck and instantly killed by an automobile as he stepped from a surface car on August 14, aged 54.

Dr. Edward B. Coburn of New York City, a graduate of Albany Medical College in 1890, a member of the American Medical Association, New York Academy of Medicine, Surgeon to the New Amsterdam Eye and Ear and Cornell Dispensaries, died on August 10, aged 43.

Dr. Paul Georges Dieulafoy of Toulouse, a member of the French Academy of Medicine and of the Legion of Honor, died August 16, aged 72.

Dr. James J. Gleeson of New Haven, Conn., a graduate of the University of Pennsylvania in 1898, died August 13.

Dr. Charles Voorhees Butler of New Brunswick, N. J., a graduate of New York University Medical College in 1893, died in Paris, France, August 17, of pyemia following a carbuncle.

Dr. Brayton Muscott of Anacortes, Wash., was accidentally shot and killed August 5, aged 42.

Dr. Nathan J. Davis of Somerville, Mass., a graduate of Harvard Medical College in 1871, died August 9, aged 67.

Dr. J. Solomon Smith of Denver, Col., a graduate of the University of Louisville, Ky., 1880, died at Excelsior Springs, Mo., August 3, aged 60.

Dr. William Hope Davis of San Antonio, Tex., a graduate of Eclectric Medical Institute, Cincinnati, 1865, died August 5, aged 74.

Correspondence.

LECTURES ON INEBRIETY AND ALCOHOLISM.

To the Editor of the Medical Record:

Sir:—A new phase of public hygienic lectures has come into prominence this year and is evidently going to attain great proportions in the near future. In July a remarkable series of addresses were given to public audiences in Birmingham and Manchester, preceding and during the session of the British Medical Association. These addresses were arranged by a committee with the object of having leading medical men address the public on the alcoholic problem. Fifty different physicians from all over the British Isles accepted these invitations and spoke at churches, halls, and other places on alcohol

and its effects. Among the prominent speakers were Sir Victor Horsley of London, Dr. Hyslop, Robert Jones, Basil Price, Dr. Eccles, Sims Woodhead of Cambridge, Dr. Sunderland, Claude Taylor, and others. Every large city of the British Isles was represented by some leading physician who discussed alcohol and its effects on the human body in a most satisfactory way. This is the first time so large a number of medical men was called upon to discuss the alcoholic problem before lay audiences. The temperance journals gave full reports of these lectures, which, in many respects, are the most startling innovation noted in the conservative profession of England. In this country a similar movement began at Atlantic City at the meeting of the American Medical Association in 1909. Six different physicians delivered addresses on the alcoholic problem in the various churches and halls of that city. This movement was under the auspices of the American Society for the Study of Alcohol and Other Narcotics, and grew out of the request of temperance and philanthropic workers to have some medical instruction along the lines of their work. In 1910 the meeting at St. Louis showed an increased interest. Nine physicians spoke in more than a dozen churches and halls on the Sunday before the association met and during the week of the meeting. At the meeting at Los Angeles this year the effort was continued, but owing to the absence of many of the leaders only five physicians spoke specifically on the alcoholic problem in the halls and churches. It was noted that more than a dozen physicians gave addresses on other hygienic subjects in the various churches and halls which attracted a great deal of attention.

Evidently a new movement has begun and the lay public look to physicians for instruction on the various subjects of hygiene and sanitary science, particularly at the time of the great meetings. The success of the movement in England will give new impetus to the work in this country. This is but a natural outlook where so many physicians gather in great conventions, that they should address the public and popular audience on questions that are of vital interest. The alcoholic problem as well as the great social evils are subjects that become more and more vital and the public interest to hear the leaders of the profession on these topics should be encouraged as the beginning of a wider movement that will react to give the profession greater power and force in public estimation.

T. D. Crothers, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE MEDICAL CONFERENCE—THE INSURANCE BILL IN THE HOUSE OF COMMONS COMMITTEE—SUNDAY FUND—MEDALS OF THE ROYAL COLLEGE OF PHYSICIANS.

London, August 4, 1911.

The medical meeting at Birmingham has passed and been a successful one—some 1,300 members are said to have attended. Next year's meeting is to be at Liverpool and Sir James Barr, consulting physician to the Royal Infirmary, has been elected as president for 1912.

Some London members returned to town on Friday or Saturday, but others made Birmingham the starting place for their holiday. Many took the week-end at home and then began their trip. One does not therefore see many of the returned members or hear as much as one might expect about the proceedings. As to the political discussion the interest has been transferred to the House of Commons, as you will see below. There the points insisted on by the association have had to be met.

Of the sections the surgical appears to have been the most attractive and this is only what might be expected, considering how greatly surgery has encroached on the domain of medicine. It is unsafe now to pronounce any area of the body as inaccessible to the surgeon.

The special sections were of course attended chiefly, if not exclusively, by those devoted to the several branches, but complaints are being made that they were too numerous—no less than 16 sections all sitting at the same time. It was, therefore, impossible for anyone to fully attend more than one. Many of the papers read had a wide interest, but it will be long before some of them can be published in the *Journal*, of which indeed they will be the pabulum for the year.

August opened in Parliament with the Insurance Bill in committee for the 10th day, 118 pages of amendments on the paper. Eleven clauses had been passed, and the whole available time was devoted to the 12th. This deals with insured patients in hospitals and provides that no payment be made to them, although they have paid their premiums. There was a long discussion on this and further on the danger that the bill would cripple or destroy valuable hospitals.

It was maintained that the managers of the principal hospitals in the Midlands estimated they would lose 50 or 60 per cent. of their income, and in one case 70, and another perhaps more. Mr. Lloyd George pooh-poohed the fears of the managers and said many persons would pass from the charge of their hospitals to that of the insurance fund, so they might anticipate relief from a heavy burden. He did not see why workingmen should give less to hospitals than they had done, and denied that employers would subscribe less freely. The hospital managers say, on the contrary, that when both these classes are compelled to pay so much a week they will consider they have done their duty. But the next day (Tuesday), on resumption of the debate, the Chancellor agreed that the amount due to an inpatient, might, if he had no dependants, go toward his maintainance in the hospital.

The next change was then taken up, which proposed that the medical benefits should be administered by the friendly approved societies in the cases of their own members. An amendment was moved by Dr. Addison in favor of transferring the administration of medical benefits exclusively to the local Health Committee. Speaking as a medical man, he told the government that without some such change the scheme would be imperilled, for most practitioners had very strong objections to be controlled by the societies. He was supported in various parts of the House, but some labor members rather objected. Mr. Lloyd George admitted that he was personally in favor of Dr. Addison's view, and believed it to be the general opinion of the House, but the government whips would not "tell" in the division upon it.

In the end Dr. Addison's amendment was carried by 387 votes to 15, the announcement of the figures giving rise to much laughter and bantering cries of "resign."

On Wednesday the committee came to the clause dealing with the income of insured persons. Sir

P. Magnus, Member for the London University, moved to confine medical benefit to those whose incomes did not exceed £104 per annum. This, he urged, would include all the really poor and leave out those who could afford to make their own arrangements for medical attendance and would mostly prefer to do so. He told the House that if passed without some such amendment the bill would absolutely ruin a great proportion of medical men. To prevent unfairness he would later move that the excluded persons should receive an equivalent to medical attendance.

Mr. Lloyd George was strongly opposed to any such modification of the provisions of the bill, and he said that a man with 30 shillings a week in the country was very much better off than one with £2 in London.

Sir R. Finlay, Member for Edinburgh and St. Andrews Universities, said the great flaw of the bill was that it proposed to perpetuate the contract system of medical practice, which was condemned by everyone who had had any experience with it. The payment of a fee promoted a patient's self-respect and prevented unreasonable demands being made. In many ways, he said, the bill was a retrograde measure as far as national health was concerned.

Dr. Addison moved an amendment under which it was left to the local Health Committee to fix income limits, and this was eventually adopted by a majority of 278 votes to 41. In the meantime the committee had agreed that all medical men who so desired should be placed on the lists of those who agreed to treat insured persons, and these last could select from the list their doctor if he consented to attend. Amendments were also inserted to protect medical institutions and to give the insured the right of choosing their own chemists and druggists.

It should not be forgotten that many other interests than the medical are affected by the Insurance Scheme. Four more deputations went to the Chancellor to make objections on behalf of local authorities. The Trades Unionists and the Socialists and Labor Party generally are beginning to pick holes, and some are advising delay or the division ot the bill into two. But the Chancellor is obstinate on this point, and it is said he will call in the closure and force it through this session, though he may have to propose amendments in the next. It seems he might have been wiser to postpone a consideration of the medical part, as all along desired by the profession, to allow time for a thorough discussion of the measure.

A meeting of the Hospital Sunday Fund was held on Tuesday, when it appeared that a serious falling off of contributions had occurred. It was suggested that absence from home on the day of the collection accounted for some of the decrease, which amounted to as much as £6,000. Others blamed the Insurance Bill and ridiculed Mr. Lloyd George's optimistic assurances that the workmen and their employers would never reduce their subscriptions.

The Royal College of Physicians has awarded the Baly Medal to Professor Halliburton, of King's College. This is given every alternate year for distinction in physiology. The college has also awarded the Bisset Hawkins Medal (or triennial distinction) to Dr. Clement Dukes, for work in sanitary science.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

THE NATURE OF RIGOR MORTIS—PHOTOGRAPHY OF THE EYEGROUNDS—CONGENITAL DEFECTS OF THE SKULL—TREATMENT OF OSTEOMALACIA WITH HYPOPHYSIS EXTRACT.

VIENNA, August 1, 1911.

THE nature of rigor mortis and of its dissolution has been studied by Otto V. Furth and Em. Lenk. Heretofore rigor mortis has been regarded as the result of the coagulation of the muscle plasma, or as an equivalent of the contractile state. P. Saxl had shown that some time after death the greater portion of the muscle protein is transformed into a substance that is soluble with great difficulty. If muscle is extracted with ammonium chloride, seven-eighths of the former goes into solution; if this experiment is performed six to nine hours after death, only one-half of the muscle is dissolved. The coagulation theory fails to explain certain phenomena, particularly the physiological cessation of rigor mortis. Certain substances, such as quinine, chloroform, and sodium monobromacetate, produce rigor mortis and coagulation of the muscle plasma.

Sodium chloride evokes rigor mortis, but inhibits coagulation of protein; while compounds of rhodium and sodium salicylate favor the coagulation of muscle plasma, but do not hasten rigor mortis. The formation of a precipitate in muscle plasma occurs later than the incidence of rigor mortis. The physiological cessation of the latter has been explained on the basis of decomposition, the formation of acids, or autolytic processes in the muscle. These hypotheses are not supported by the above investigations. Fürth and Lenk believe that rigor mortis is probably the result of a swelling up of the muscle fibrils caused by the formation post mortem of acids. The fibrils swell up and become shorter. The cessation of rigor mortis is brought about by the coagulation of the muscle plasma, which has been shown to proceed *pari passu* with the subsidence of the fibrillar swelling. Between 20 and 30 hours after death the muscle reaches the maximum of its power of imbibing water, which power then rapidly diminishes.

All factors that favor the coagulation of muscle plasma also hasten the subsidence of rigor mortis. Both of these processes are hastened in the incubator, while, according to V. Eiselberg, rigor mortis is retarded by section of the nerves. In an atmosphere of oxygen rigor mortis does not appear, while strangely no lactic acid is formed, and whatever lactic acid is present is destroyed. Perfusion of the muscle with Ringer's solution, which washes out the lactic acid, removes the condition of rigor mortis. Heat rigor is a phenomenon differing from rigor mortis, depending upon the coagulation in large lumps of the muscle plasma; such muscle is hard and white. Chemical rigor, such as is produced by quinine, sodium fluoride, chloroform, and sodium monobromacetate, has various causes, among which may be mentioned as one of the most probable the formation of acids by means of a protoplasmic poison (sodium fluoride).

The photography of the eyegrounds has been achieved by Professor Friedrich Dimmer. Efforts in this direction are as old as the use of the ophthal-

moscope. The advantage of this procedure consists in the rapid elaboration of the picture, which would be subject to metric analysis. Difficulties that present themselves in photography of the retina are retinal reflexes and the changes in focus, such as occur in glaucoma, swelling of the papilla, and separation of the retina. To counteract the reflexes polarized light was employed, but this method provided insufficient light. Better was the use of screens. Gerloff, in 1888, was the first to demonstrate a photograph of the retina. In 1899 Dimmer communicated his results, and in 1902 he demonstrated instantaneous photographs. The apparatus is a complicated one, providing an exposure of 1/20 of a second, and giving a picture that is enlarged from three to four times, and that comprises a visual area from five to six times the diameter of the papilla.

"Congenital Deficiencies of the Skull" is the title of a paper by Hochsinger, who summarizes his conclusions as follows:—There are three forms: (1) the type depending upon excess of intrauterine, intracranial pressure resulting from a preexisting hydrocephalus or some ordinary malformation; (2) congenital softness of the skull of rachitic origin; (3) congenital thinness of the cranial bones resulting from a fetal panostitis. In softness of the skull bones the bone near the sutures is soft and there is frequently craniotabes. In genuine deficiency of the cranial bones there are bone ossification defects without rickets, and the bony margins are hard. In many cases there is also spina bifida, which would indicate a fetal hydromyelia in conjunction with hydrocephalus. Genuine defects in the skull may in some cases be results of simple inhibition of development. Congenital syphilis may also be one of the causes of cranial defects.

The treatment of osteomalacia was the subject of an investigation by Dr. Bab in Professor Wertheim's clinic. He had had exceptional success in a most severe case of osteomalacia, to whom he had administered subcutaneously 2 c.c. of pituitrin daily. This form of therapy was suggested by the fundamental antagonism between acromegaly and osteomalacia, and between the hypophyseal and ovarian functions. In acromegaly there occur atrophy of the ovaries; amenorrhea; cure by extirpation of the hypophysis; greater incidence at the climacteric, after ovariotomy, or in the course of a sterility associated with amenorrhea; loss of sexual desire; tendency to diabetes; relationships to myxedema; therapeutic inefficiency of pituitrin, but efficacy of thyroidectin and the return of menstruation after extirpation of the hypophysis. Above all, in acromegaly there is the formation of strong bony substance.

Just the reverse of all this occurs in osteomalacia, in which there are the following manifestations: hyperfunction of the ovaries, cured by ovariotomy; greatest incidence in the period of sexual maturity, great average fertility, no disturbance of the course of gestation, preservation of the libido, absence of adrenalin glycosuria, relationships to exophthalmic goiter, therapeutic success with antithyroidin of Moebius, and softening of the bones. On the basis of an experience with eight cases the author concludes that pituitrin in the majority of the cases cures the pains and improves the general condition. In other cases the improvement proceeds only to a certain degree. In other cases there is no improvemnt.

Aspects of Abdominal Ptosis. By J. G. Mumford.
Chronic Acetanilid Poisoning a Perfectly Definite Symptom Complex. H. C. Gordinier.
Hydrocele and Its Radical Cure by the Insertion of Catgut. C. M. Whitney.
Concerning Nurse Training Schools. S. E. Parsons.
"Compression Myelitis" by an Aneurysm Occurring in a Tabetic. J. B. Ayer.

Abdominal Ptosis.—J. G. Mumford states that acquired ptosis is comparatively rare, but congenital ptosis is extremely common. The latter is found in 20 per cent. of all dissecting-room subjects. A prolapse of the stomach leads commonly to stasis, to pyloric kinking and obstruction, to toxemia, rarely to gastric tetany, frequently to loss of appetite with chronic nausea and occasional vomiting. In addition there are headaches, loss of flesh and strength, secondary anemia, changes in temperament, irritability, and neurasthenia. Prolapse of the large intestine is probably far more significant than prolapse of the small intestine. It results in chronic catarrh of the intestine, often with stercoral ulcer, with accumulations of gas, and with a distressing constipation, sometimes alternating with diarrhea. The toxemias resulting from abdominal ptosis may cause gastric and intestinal indigestion, headache, iritis, disorders of the lens, extensive mucous inflammations, neurasthenia, arthritis, and disorders of the ductless glands. Many cases of exophthalmic goiter are associated with abdominal ptosis. Treatment of prolapsed abdominal viscera consists in postures, the wearing of braces and belts, and operations.

Chronic Acetanilid Poisoning.—H. C. Gordinier states that the continuous ingestion of acetanilid or allied products causes cyanosis; enlargement of the heart, spleen and liver; a secondary anemia, with a moderate polynucleosis; the drop of blood obtained from the ear or finger is of a bluish black or chocolate color; the urine is dark brown or black in color and gives the characteristic indophenol reaction. Acetanilid is a most virulent hemolytic poison.

Treatment of Hydrocele.—C. M. Whitney states that this may be palliative or radical. The former consists in tapping the sac. The radical methods are of two kinds, operative and non-operative. The latter consist in tapping the sac and injecting into it a fluid or inserting a substance which causes an acute inflammation with adhesion of its walls and obliteration of its cavity. One method is the introduction of sterile catgut. Another is the injection of pure carbolic acid. The third and oldest method is the injection of tincture of iodine. The author concludes from his experience, involving the treatment of 196 cases, that one can reasonably expect a larger percentage of cures from the insertion of sterile catgut than from any other method.

Nurses' Training Schools.—S. E. Parsons calls attention to a few of the important facts to be considered relative to the selection by a young woman of a suitable training school.

Compression Myelitis.—J. B. Ayer reports the case of a colored male aged 49 years, who for two years had had cramp-like pains, mostly in the limbs, and for less than a month had had sensory disturbances and loss of sphincter control. Pupils were unequal, reacted sluggishly to light, and knee-jerks were absent. There was a large pulsating aneurysm in the back. There were two cord lesions; one of ancient date, tabetiform in character; the other, acute and caused by pressure of the aneurysm.

Treatment of Gastric Ulcers by Lenbartz's Method. J. J. Gilbride.
Report of Two Cases of Occipital Abscess with Wernicke's Pupillary Phenomenon. I. Strauss.

Chronic Appendicitis.—N. Jacobson reports a series of cases in which the early history was always indefinite, the symptoms pointing to the stomach, duodenum, gall-bladder, or the large bowel, and a period varying from one year to several years elapsed before any evidence strongly suggested appendicular disturbance.

Typhoid Bacillus Cholecystitis.—B. Holmes concludes that typhoid bacillus cholecystitis is an invariable attendant on typhoid fever. Clinical (obstructive) cholecystitis occurs when the cystic duct is obstructed. The gall-bladder often retains the infection long after the typhoid septicemia and typhoid enteritis have passed away, and then the typhoid bacilli may, by use of cholegogues, be found in the stools. The fate of a typhoid bacillus cholecystitis is so uncertain and so surrounded with danger that the fear of a surgical operation in the course or at the beginning of typhoid fever should not be given too much weight. The cholecystostomy should be promptly and quickly performed with the minimum of anesthetic and the minimum of traumatism. No attempt should be made during typhoid fever to remove stones from the cystic duct. A later cholecystectomy will rarely be necessary.

Esthetics of Surgery.—A. M. Crispin believes that surgery possesses all the elements which compose the fine arts besides its highly altruistic tendencies. It is decidedly utilitarian, increasing the happiness of the individual, relieving him of malformations, repairing and creating new conditions, augmenting their beauty, saving or prolonging life. He also finds it to be superior to the other arts in that its aim is not only the weal or woe of the individual but, more important still, the betterment and conservation of the race.

Salvarsan.—H. Goldenberg and D. J. Kaliski conclude that salvarsan has a large sphere of usefulness, acting beneficially on all forms of active specific lesions. They recommend strongly the use of both salvarsan and mercury, a thorough course of the latter following one or two injections of salvarsan, and, finally, an additional injection of salvarsan.

Medical Aspects of Life Insurance.—By A. Moss. (See page 444.)

Prevention of Prostitution.—M. Glasgow states that when women become economically independent, when they are carefully educated and trained for the occupations they have elected, then the days of prostitution will be numbered.

Treatment of Gastric Ulcer by Lenhartz's Method.—J. J. Gilbride describes this method of treatment and states that it relives the pain in from three to eight days in ordinary cases. The patient is cured not only of his ulcer but also of his anemia and debility. The treatment can be applied at the home of the patient without the aid of a trained nurse.

Occipital Abscess.—I. Strauss reports two cases of this condition, in both of which hemianopsia was present, together with the hemiopic pupillary reaction, which is usually not present in lesions of the occipital lobe. This reaction, which is known as Wernicke's pupillary phenomenon, is as follows: When hemianopsia is due to a lesion of the optic tract anywhere from the chiasm to the external geniculate body, the pupillary reflex to light is absent when the light is thrown on the blind half of the retina, but when the lesion is between the geniculate body and the cortex around the calcarine fissure there is pupillary response to light in the blind half of the retina.

Intratracheal Insufflation.—S. J. Meltzer states that this method consists in the introduction deep into the trachea of a flexible elastic tube, the diameter of which has to be much smaller than the lumen of the trachea, and the driving through the tube of a nearly continuous stream of air which returns through the space between the tube and the walls of the trachea. The method keeps up an efficient respiration, overcomes the difficulties presented by double pneumothorax, and offers a reliable method for anesthesia, especially by ether.

Appendicular Abscess. By Van B. Knott. See MEDICAL RECORD, July 8, 1911, page 100.

Subphrenic Abscess Following Appendicitis.—G. G. Ross describes three groups of cases: (1) Those occurring or found at operation, *i.e.* an immediate and primary complication of the disease; (2) those making themselves manifest as late or postoperative sequelæ during the postoperative stadium; and (3) cases occurring a long time after the primary infection. In giving a list of symptoms of subphrenic abscess, the author places first sepsis following an operation for appendicitis without evidence of its cause, the primary incision progressing favorably. Second in importance to the symptoms of general sepsis are the signs of pulmonary involvement at the base of the lungs. The most valuable of these indications is the presence of a more or less marked area of dulness. In addition to this, the other indications of a collection in the pleural cavity are often found, *i.e.* lessened breath sounds and fremitus. The abdominal symptoms, when present, are those of any collection within the abdomen. The treatment of subphrenic abscess following appendicitis is that of any other collection within the abdominal cavity.

Tumors of the Mesentery.—By H. H. Royster. See MEDICAL RECORD, July 8, 1911, page 102.

Technique of Operations for Hemorrhoids.—A. B. Cooke states that the most important points in this technique are complete hemostasis, immediate closure of the operative wounds, preservation of the function of the parts, permanency of cure, and due consideration of the factors of safety, simplicity of technique, time required for recovery, and the amount of postoperative pain.

Tendon and Fascia Transplantation.—By D. Lewis and C. B. Davis. See MEDICAL RECORD, July 8, 1911, page 100.

Climate and Middle-Ear Diseases.—J. J. Pattee describes the atmospheric and climatic conditions of the Rocky Mountain region in Arizona, New Mexico, and Colorado, and points out how they may affect middle-ear diseases for the better. The atmospheric conditions are stimulating to the respiratory, circulatory, and nervous systems, and the vasomotor apparatus is therefore usually in a healthy condition and the body resists taking cold.

Nose and Throat and Middle-Ear Disease.—W. R. Murray emphasizes the following points: (1) A very large proportion of people are subject to some aural de-

fect; disease of the middle ear furnishes from 65 to 70 per cent. of all aural diseases, and of all cases of deafness the middle ear is responsible for about 85 per cent. (2) Of all sources of involvement of the middle ear, about 90 per cent. are caused by involvement through the Eustachian tube.

Nose and Throat and Middle-Ear Deafness.—J. F. Barnhill states that the continued presence of any obstructive growth in the nasopharynx is a menace to the integrity of hearing. Before aural disease appears in the child the removal of adenoids, etc., will be prophylactic. After the disease has started, but before it has become so great as to cause serious or permanent damage, the case is still hopeful if the obstruction and other abnormalities are removed, but later, when tissue changes are palpable and long standing, the prospect of relief gradually decreases to nothing.

Refraction Changes in Diabetes.—C. D. Wescott and J. B. Ellis call attention to the fact that the refraction not only may be increased in diabetes, but that it may be diminished; and that the changes bear no necessary relation to the amount of sugar in the urine.

Certified and Pasteurized Butter.—A. F. Hess states that the public has not been warned against the dangers of contaminated butter as it has against those of contaminated milk, and admits that these dangers are of secondary importance though still worth heeding. The certification of butter should impose the same requirements as those for certified milk.

Diagnosis of Pancreatic Disease.—L. G. Heyn describes the various methods of testing for the presence of the ferments in the stools in pancreatic disease. The two ferments are trypsin and amylopsin, and the absence of either from the stools would point to pancreas obstruction or insufficiency.

Twisting of Cord in Utero.—H. W. Froehlich reports a case of death of a six-months' fetus from this cause.

School Health. F. E. Fremantle.
On Cancer, Cancer Regarded as an Adaptive Response on the Part of Certain Cells or Cell Groups to Environmental Change, and as the Result of a Process of Variation and Selection of an "Inter-" or "Intra-" Cellular Kind. C. J. Bond.
Diffused Cancer of the Female Mammary and Thoracic Integument ("Cancer en Cuirasse"). Sir G. T. Beatson.
A Case of Toxemia of Uncertain Origin, and Its Treatment by Sea-water Injection. I. C. Maclean and L. de C. Harston.

School Health.—F. E. Fremantle states that school children are entrusted to the State for a large part of their malleable life and that consequently the State has both a responsibility and an opportunity of molding its future citizens in accordance with the rules of health and medical experience. The main objects are three: (1) The health and future ability of each child. (2) The healthy influence of each child on its neighbor. (3) A statistical record by which to compare the health of different schools and communities or of different years and periods, and so to arrive at the effect of different social conditions in promoting or retarding health. The main principles to be observed are therefore as follows: (1) The gradual installation of the school doctor as the general and responsible guardian of the school health. (2) The gradual installation of the school teacher as the daily inspector of the children's health, and as the prime agent in the inculcation, both by reason and habit, of school hygiene. (3) Continuity of medical inspection and record throughout the school life of each child. (4) A high degree of clinical experience, public spirit, and personal authority in the medical inspector. (5) Intimate connection between those in charge of the child's health at school (the head-teacher and medical inspector) and those at home (parents and sanitary authority). (6) Sufficient participation by those in charge of school health in the whole work of the educational machine. (7) Accuracy, a uniform common-sense standard, and an efficient method of recording the facts observed; care in their compilation; caution in the deduction of results, and wisdom in the presentation both of facts and conclusions to the authority and to the public.

Cancer.—C. J. Bond believes that cancer, like all "new growth," must be regarded in the light of a response of an adaptive kind on the part of certain cells or cell-groups of varying potentiality to changes in their environment. He suggests that in epithelial cancer, at any rate, this response takes place under the same conditions as those which are associated with the occurrence of variation and selection among other organisms when exposed to environmental change and where evolution of new characters is taking place, especially in response to changes in the external environment. And the suggestion is therefore made that blastomatosis, including cancer and certain other forms of cell multiplication, takes place under the influence of the same evolutionary factors—namely, variation and selection of the "inter-" or "intra-" cellular kind. The old inquiry still remains: the ascertainment of the kind of environmental influence on the one hand, and the special factor, hereditary or acquired, in cell potentiality on the other, which are independently or conjointly responsible for initiating the process whereby the new characters arise "innately" in, or are "acquired" by, cells engaged in neoplasmic growth.

"Cancer en Cuirasse."—Sir. G. T. Beatson concludes that in cases of mammary carcinoma there may be a cancerous invasion of the lymphatics of the skin exhibiting all the symptoms of Velpeau's "cancer en cuirasse." The cutaneous lymphatics have to be reckoned with as a possible area of dissemination of the disease.

Sea-Water Treatment of Toxemia.—I. C. Maclean and L. de C. Harston report the case of a female patient aged 60 years, suffering from what appeared to be infective arthritis, accompanied by colitis and endocarditis. Blood cultures were sterile. The administration of autogenous *Bacillus coli* vaccines had no effect. Improvement followed the subcutaneous injection of sea-water, twice a week, in doses of from 25 to 50 c.c., until 30 injections were given.

Complications of Rheumatism in Childhood. F. J. Poynton.
Four Cases Illustrative of Certain Points in Psychoanalysis. H. Wingfield.
Retinoscopy without Atropine, and Some Observations on Ocular Headaches. J. A. Wilson.

Complications of Rheumatism in Childhood.—F. J. Poynton discusses this subject in continuation of a former paper in which he referred to rheumatic rashes and purpura, venous thrombosis and early rheumatic tachycardia, mastitis and epistaxis. He now describes the following complications: pleurisy, pneumonia, and acute pulmonary edema. Bronchitis is not a complication of rheumatism. Although abdominal symptoms simulating appendicitis may occur in rheumatism, particularly in arthritis of the right hip, nevertheless appendicitis is not a frequent complication of rheumatism. Abdominal pain in rheumatism may be fascial, neuritic, or gastric. Rarely the pain results from splenic infarction. The possibility of a rheumatic peritonitis is still in dispute. There may occur a smouldering rheumatic inflammation of the cervical fasciæ and vertebral joints, with a spread of the same process to the nerve roots in the neighborhood. This may simulate spinal caries, and may have something to do with the clinical history of spondylitis rhizomélique.

Psychoanalysis.—H. Wingfield reports four cases illustrating certain points in this process.

Retinoscopy Without Atropine.—J. A. Wilson points

out the advantages of this procedure as demonstrated in 100 children. He also discusses the subject of ocular headache and states that whatever may be due to error of refraction, inefficient accommodation, disturbance of muscle balance, and their interrelations, there is behind all this a varying quantity, a background of susceptibility which belongs to the province of the physician or the general medical practitioner.

Berliner klinische Wochenschrift.

July 31, 1911.

Mutation Phenomena in Bacteria.—Baerthlein has continued his labors in this field, working chiefly with cholera vibriones and typhoid bacilli. He has isolated several types of the former which behave differently in regard to hemolysis. The cultures differ in appearance even to the naked eye. Differences as to agglutination, while evident, are very slight. The mutations of Eberth's bacillus have no connection with paratayphoid bacilli, which are looked upon as quite distinct. A number of such mutations are recorded under such designations as the typhus Krause, t. Stettin, etc., while in other cases numbers are used for designation (194, 234). These mutations are so numerous than they are even subdivided into groups. The chief characteristics are morphological, and the cultures are even distinguishable to the naked eye. The biological reactions do not differ notably. More time is required to obtain these conditions than is the case with cholera vibriones. There are various mutations of the Shiga dysentery bacillus, one of which behaves much like a typhus culture. The paratyphoid bacilli, already separated into two quite distinct forms, show many mutations, named for different investigators or clinics. Some of these are already regarded as specific germs, such as the bacillus of mouse typhoid, that of psittacosis, etc. The practical bearing is largely limited, thus far, to comparative pathology.

Ichthyotoxic Conjunctivitis.—Steindorff refers chiefly to eel blood conjunctivitis. Eel serum is known to be toxic by fishermen, fish dealers, and cooks, *i.e.* locally toxic, but only recently have cases of conjunctivitis from this source been reported. The author has seen two such cases. When the blood spurts into the eye of the fish dresser, reddening and smarting result, and eventually a typical conjunctivitis is present. In the laboratory it has long been known that eel serum contains a toxic substance which cannot be isolated but is inherent in the serum. The latter also exerts a hemolytic action in proportion to its toxicity. It is known that the leech is naturally immune to these activities. The power of the serum in causing conjunctivitis has been shown in the laboratory. Other sera, as far as known, do not cause this phenomenon. Heating to 58° C. does not destroy the toxic principle. The author does not bring the subject into the realm of fish poisoning from ingestion, which may be regarded as more or less anaphylactic in character. As far as known, the toxin of eel serum induces all its effects without involving this question.

An Anti-Epileptic.—Lion claims to have cured epilepsy by injecting subcutaneously a combination of a brain extract with arsenic. The former is not specified as to character and manufacture, but it is intimated that any cerebral extract will answer the purpose. The arsenic is given in the form of sodium cacodylate. The method of combination is not stated. This form of treatment is advocated tentatively. The results quoted seem about on a par with those obtained by bromide medication, while it is admitted that the treatment is very burdensome, even if quite harmless. The author seems unable to cite any *a priori* reason for exhibiting arsenic in epilepsy.

Iodine Injections in Gonorrheal Arthritis.—Hildebrand has revived this old remedy, which was used nearly a century ago for ordinary acute synovitis and later for tuberculous arthritis, while it has been the accepted remedy for hydrocele. The tincture or watery solution respectively is believed to destroy all gonococci on the surface and perhaps those more deeply seated; since the penetrating power of iodine is shown by its rapid appearance in the urine. The author has practised the injections in the knee and hip joints, among others, for some nine months. The joints swell rapidly, but the swelling quickly recedes and no unpleasant consequences result. Pus in the joint furnishes a contraindication. The author has used a 5 per cent. tincture.

Münchener medizinische Wochenschrift.

August 1, 1911.

Vasoconstrictor Substance in the Serum of Rachitis, Tetany, etc.—The Drs. Hirschfeld have examined many sera from subjects with rickets, tetany, and the exudative diathesis. These conditions naturally tend to occur side by side in the same subjects. Thus in an infant with tetany eclampsia, laryngospasm, and eczema coexisted. In another with diagnosis of exudative diathesis (eczema) there was slight rachitis. In the third, with main diagnosis of rachitis, the facialis phenomenon was inducible. Therefore these children represented a common condition in which the bone affections, spasmophilia, and the exudative diathesis were often all three represented, and usually two at least were present. The power of the serum to cause vasoconstriction in the frog's vessels was three or four times as great as that of normal serum, and differed but little with the diagnosis. If tetany was present in a well-marked form the constricting power was somewhat greater than in simple rickets or exudative diathesis, but the average proportion was only 7.1 to 5.8. Individual cases of rickets, etc., showed as great or greater an index than any individual case of tetany. Whence comes this vasoconstricting substance? The latter has been thought to be an excess of adrenalin from the parathyroids, due to some disturbance in the latter, which may be either primary or due in turn to some anomaly of the adrenals.

Thyreoses (continued).—Krecke, who in a previous number considered thyreoses with predominance of cardiac symptoms, proceeds with a second type in which the nervous system suffers chiefly. It is, of course, common to see both the heart and nervous system notably affected in Graves' disease, and the author naturally refers to cases in which the tachycardia is not pronounced, while the nerves are markedly implicated. We also see in simple goiter an entire series of nervous phenomena due to hyperthyreosis. In a case which presents itself with general nervousness an overlooked small goiter may be recognized. The leading symptoms are a fine tremor of the hands, motor unrest, excitability, and psychic disturbances. In some cases of apparent neurasthenia and hysteria antithyroidin by relieving the symptoms points to the true nature of the malady, even when an enlarged thyroid cannot be made out. In thyreoses with disturbed nutrition, which in turn seems to depend on gastrointestinal disturbance, the author does not refer at all to myxedema, but to Basedowoid, in which loss of weight is a much more pronounced symptom than tachycardia or nervousness. If a goiter can be felt the diagnosis is not difficult. In theory iodides would intensify the symptoms, but to give them with this end in view would not be justifiable. The type last considered is thyreosis simulating iodine poisoning or so-called iodine Basedow.

Frequency of Peptic Ulcerations.—Gruber states that of late years there has been much interest in the subject of the total morbidity from peptic ulcers of the esophagus, stomach, and duodenum. Chiari found among 4,208 autopsies at Strassburg 140 cadavers with peptic lesions. These figures cover a period of ten years. The percent-

age is about 4. In other cities similar figures range from 2 to 7 per cent. Males predominated by a comfortable margin, and in a series of 115 cases the condition was recognized clinically in only 18. Cicatrices are included in the material, no less than actual ulcers. The affection is one which flourishes between 40 and 70 years of age, and may be almost disregarded in children under ten years. Over one-half of the subjects suffered from pathological alterations in the heart and vessels, but this includes slight as well as marked changes. Healed or manifest tuberculosis was present in about one-third of all cases. In 14 per cent. of all cases the ulcers were perforating. Nothing new is developed as to frequency according to site.

Deutsche medizinische Wochenschrift.

July 27 and August 3, 1911.

Physiological Pathology of the Bechterew-Strümpell Disease.—Plesch has analyzed four cases of chronic rigidity of the spine, a condition which however simple in itself, leads to the most tragic consequences. In all four cases there was expiratory fixation of the thorax, so that respiration was chiefly diaphragmatic. It has evidently been held a fact that the fatal termination in these cases results directly from the disease, for the author professes great surprise at his discovery. As a result of the stiffening of the vertebral column many muscles undergo atrophy from disuse, while the addition of polyneuritis to the spondylitis causes further trophic disturbances, while contractures supervene. The interference with respiration leads to progressive oxygen hunger, a fact which could readily be demonstrated. The patients die from gradual failure of the respiration and circulation. Any rational treatment must include the mobilization of the ribs by resection at the posterior costal articulation.

Treatment of Hay Fever by Bilateral Resection of the Anterior Ethmoidal Nerve.—Albrecht reviews the work of the English surgeon, Jonge, in this field, and gives an experience of his own in which the patient became distinctly worse after intervention. A second patient may have been benefited, but as he was not exposed to pollen the following summer no conclusion could be drawn as to the character of the results. The author thinks the operation without sufficient anatomical justification, as shown by some markedly negative results. Scars remain, and in one of the author's cases became keloidal. Double vision resulted in one case, due, it would appear, to postoperative hematoma, which required months for its absorption. It is necessary to prevent this accident that the trochea be spared. Postoperative neuralgia is also prone to develop in this type of intervention, which is naturally similar to that required for suppuration in the ethmoidal and frontal sinuses.

Determination of Gastric Acidity by the X-Ray.—Schlesinger endeavors to make the gastric juice visible by having the patient drink a solution of sodium bicarbonate. The rays first give an idea of the amount of gastric juice in a fasting stomach or the amount of chyme in the digesting stomach. The amount of effervescence, as estimated by the shadow, is a measure of the free acid in the stomach. The method may be used in cases unsuitable for sounding or as a corrective for the usual test. A diagram shows very plainly the three strata in the shadow. The lower half of the stomach shows the stomach contents blackened with bismuth. The author usually prefers to have the patient take into his empty stomach a pulp containing the latter. The stomach is at once photographed. About an hour afterward a second exposure is made, whereupon an intermediary layer of gastric secretion is visible above the bismuth. The soda solution is then drunk, and two minutes later a third exposure is made, whereupon an upper stratum of gas is seen filling the upper part of the stomach. Although the author only claims a qualitative value for the test, he gives numerous quantities obtained by measuring the shadows.

Treatment of Gastric Hyperacidity with H_2O_2.—Prof. Winternitz states that pure solutions of hydrogen peroxide will lower the gastric acidity even when the concentration of the latter is but feeble. The action, however, is very transitory. For this and other reasons not described he has virtually abandoned the use of the remedy as a step toward cure. He seems to have originated this treatment, and as others report favorably on it it has been renounced only after a thorough trial. He thinks it better to leave the remedy to those who find benefit from it.

Senile Affections of the Central Nervous System.—Spielmeyer considers these in a serial article without apparent effort at new propaganda. He deals largely with senile dementia, with especial reference to Alsheimer's researches. Attempts have been successfully made to separate senile dementia into different types, based largely on histopathological findings. It is known that an essential type occurs which is quite independent of arteriosclerosis. Retrograde changes occur when the nerve substance is completely exhausted and in the form of plaques, which are readily revealed at autopsy by applying certain stains to the tissues, chiefly the middle layer of the cortex. They are most numerous in the frontal lobe and cornua of Ammon. These plaques, while pathognomonic in some degree, do not furnish the sole anatomical base for senile dementia. Despite the radical difference in their nature there are many points of close resemblance between the latter affection and paresis. Both have the same predilection areas, and even in the histopathology there are certain analogies. Clinically, of course, paresis has always been considered as a form of dementia. Alsheimer and others have described forms of atypical senile dementia due to special local involvement. What clinically is known as essential senile dementia represents only a rapid accentuation of a normal involutionary process. A special type of senile involution begins in the blood-vessels when these are, so to speak, worn out. The change is known as atherosclerosis. Two types are recognized. In the first the cortex is the seat, while the second, which is not much known, attacks the bulb. It seems assured that the cortical changes which are secondary to atherosclerosis are quite different from those of essential senile dementia. Nor do these two conditions exhaust the subject of the anatomical substratum. Other affections occur, but have not yet been isolated.

Syphilitic Reinfection after a Salvarsan Cure.—Krefting discusses the old teaching as to reinfection, and after stating that most of the recorded cases came to be regarded as examples of pseudochancre and chancre redux admits that a certain number of cases were evidently genuine. Both the mercurial and the spontaneous recoveries from syphilis which would make reinfection possible were slow and uncertain, and were without other criteria of cure. To-day we have in salvarsan a possible rapid and abortive cure, and the Wassermann reaction as an independent test of curability or cure when properly estimated. We further have the criterion furnished by the presence or absence of the spirochete in a supposed primary lesion. In a case cited by the author the patient originally had a chancre teeming with spirochetes. The Wassermann reaction had not yet become positive. Conditions were ideal for aborting the disease with salvarsan given intravenously in three injections at intervals of twelve days and thirty-six days respectively. No secondary symptoms developed. The Wassermann never became positive. Patient was regarded as cured April 30. The following June he contracted two new chancres, the serum from which contained spirochetes in abundance. The Wassermann reaction was already weakly positive.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

HYGIENIC SURROUNDINGS.

The question of hygienic surroundings is about the first to excite the interest of the examiner upon his arrival at the appointed place and he usually has an opportunity to look around while waiting for the applicant to appear. An individual who is willing and able to apply for life insurance is so apt to understand and observe the laws of hygiene that the examiner, as a rule, pays but little attention to the sanitary surroundings of the applicant. The unsatisfactory conditions described further on are encountered at times, however, and it is therefore not a good idea to take it for granted that the environment is always above criticism. While the examiner can only make a personal investigation, as a rule, at the place where he meets the applicant, he ought to inquire into the sanitary conditions existing at the residence or place of business, as the case may be, or in regard to both places, if the applicant comes to the examiner's office.

Residence.—Applications numerous enough to excite comment are received from persons living in quarters which, by reason of the squalor, filth, and overcrowding found there, are so distinctly unsanitary that the occupants become undesirable risks. These applicants are usually found among the foreign elements of the population in the larger cities. Their one and only idea is the accumulation of money, and they are absolutely ignorant of or indifferent to the most ordinary laws of hygiene. Yet, strange as it may seem, they are keenly alive to the advantages derived from life insurance and willing to pay for it. Such people may, furthermore, be counted upon to choose food unfit to eat and more or less devoid of nourishment. We are frequently assured by the agents that these people live to a ripe old age in spite of their habits and environment, but the fact that a few patriarchs are found among them is easily explained by the law allowing the survival of the fittest. To prove how little foundation there is to such statements, we only have to remember that there are quite a number of authenticated records of individual negroes living considerably over 100 years of age, yet recent statistics of the city of Washington give a death rate of 27 per thousand among the colored peoples, while that of the whites is 15 per thousand. After all has been said, however, it remains true that human beings can exist under unfavorable circumstances, provided the conditions are not altogether bad, and the examiner will, therefore, have to make careful observations and then exercise his judgment as to whether or not he should recommend the risk. The presence of tuberculosis or other infectious diseases and the hygienic measures adopted for the protection of others should be fully reported.

Place of Business.—It is not unusual to find workers horded in places, especially the sweat shops and junk shops, which are so overcrowded, badly ventilated, damp, and poorly lighted that their health is liable to become impaired. The applicants met in such places are usually in the class described in the preceding section. The objectionable condition may be due to the occupation rather than to lack of sanitation, but as the companies have investigated the subject of occupation carefully and instituted certain restrictions, the examiner will seldom have to take any action other than noticing if the occupation has been correctly given in the application. Nevertheless, if an applicant is found exposed to any condition liable to prove dangerous to life, such, for instance, as the presence of noxious fumes, or an excess of metallic or other injurious dust, the facts should be incorporated in the medical report.

The Locality.—In the cities and towns about the only adverse conditions threatening the whole community are the rare but violent epidemics of typhoid, yellow fever, and other contagious diseases. Owing to the better understanding of preventive measures, the authorities are able to adopt the proper and effective precautions. While, then, epidemics of these diseases seldom assume so grave an outlook as to warrant the companies in even temporarily ceasing to accept business from the affected locality, nevertheless it remains for the examiner to advise the home office of the existence of any epidemic and as to whether or not proper sanitary and preventative measures are taken by the applicant. In the country and small villages the local organization for putting preventive measures into force may be too limited to insure complete and satisfactory results, so that it will be better in the rare instances in which this condition is likely to appear, to report it.

Last, and perhaps the most important, especially in the South and Southwest, is the prevention of malaria by means of drainage and screens. Through these two measures a great deal has been accomplished in preventing the propagation of the malaria-bearing mosquito and the entrance of these insects into the house. Many people are careless, however, and when the applicant is a resident in a district where malaria of a severe type is known to occur, vigilance should be exercised in noting the surroundings, the presence of unscreened rain barrels and other vessels holding water, and whether or not the house is properly screened.

Industrial Accidents and Compensation for Them.—(See page 431.)

Medical Aspects of Life Insurance.—A. Moss emphasizes the grave responsibility that rests upon the medical examiner, who, if incapable, dishonest, or lax in his duties, threatens the very foundation of life insurance. It is important that the examiner should identify the applicant; inasmuch as many substitutions occur, a good detective ability on the part of the examiner is a valuable asset. One great fault of the examiner is indecision: the endeavor to shift the responsibility of accepting the risk upon the home office medical director. The apex of the right lung is responsible for considerable confusion in the mind of the inexperienced examiner. In order to be entirely normal the right apex must conform to the following tests: There should be neither dullness nor râles; there may be an increase of pitch in the expiratory note as one approaches the spinal column, but, if there is a uniform heightening of the pitch throughout, the apex is abnormal; there should be no increase in the vocal fremitus, except corresponding to the natural increase in pitch toward the spinal column; there should be no sunken supraclavicular space, and there should be pure vesicular breathing high up in the axillary space. Life insurance statistics show that 21 per cent. of the total mortality is due to diseases of the circulatory system, indicating a poor initial selection of risks. The errors of diagnosis where actual valvular lesions are concerned are almost negligible. The great mistake consists in failure to estimate the arterial conditions. One should take both radial pulses

simultaneously, noting carefully the condition of the arteries, the rate, the tension, and the volume. One should next elevate the applicant's right hand above the head, and examine the pulse in that position; this will sometimes reveal a Corrigan pulse. Some heart murmurs are heard only in the recumbent position. Cardiac arrhythmia is present more frequently than is supposed, and is looked upon with grave suspicion. One important question to be asked of the applicant is whether he has ever had colic. If this is acknowledged, then the examiner should elicit the following facts: Was the pain due to a transient condition, such as flatulence, constipation, or indigestion; was there a more serious cause operating, such as gastric ulcer, beginning malignant disease, hepatic or renal colic or abscess, appendicitis, etc.? Associated symptoms in any of these conditions should be inquired into. The boiling test for albumin is very untrustworthy. The moral hazard of a risk is sometimes so great that the company will reject on that ground alone; occupation may be extrahazardous, and the hygienic surroundings may be a sufficient cause for rejection. One should not reject an applicant on general principles, but should do so for a good and valid reason: if one cannot discover it in the heart, lungs, or the abdominal viscera, and the applicant still impresses one poorly, one should look for extreme anemia, chronic indigestion, or gastritis, alcoholism, plethora, arteriosclerosis, immoral habits, etc. Any of these causes, if it really exists, is sufficient reason for rejection, and should be explained fully in the report.—*New York Medical Journal*, August 12, 1911.

Life Insurance and Sanitary Science.—In an address delivered at the annual meeting of the Louisiana State Medical Society on June 1 Dr. J. H. Florence, medical director of the Great Southern Life Insurance Company, Houston, Texas, made a strong plea for better sanitation in the towns and cities of the South, approaching the subject from the insurance standpoint. It is a well-known fact, he says, that a large proportion of the profit made by life insurance companies arises from a saving in mortality; hence, the fewer the number of deaths among policyholders the more profitable the business. Therefore, it requires no thought to deduce that when the sanitary surroundings in any locality are good, and every possible agent conducive to good health and long life is used, the life insurance in that locality will be conducted upon a profitable basis The reverse also holds. Where business is put on the books from unhealthful and unsanitary localities, with all the surroundings detrimental to good health, it only remains to be said that such business is carried at a loss, or at a minimum profit. The question naturally arises: Why so much concern about the welfare of the stockholders? We may rest assured that the premiums on all policies are loaded to cover lives in unhealthful territory, also to cover those shortened by the non-observance of the laws of health. This loading is necessary to protect the companies against loss arising from unsanitary surroundings, which would not occur were the policyholders residing in localities conducive to good health. In other words, a citizenship which permits preventable diseases and unsanitary conditions to exist, and death to run rampant, must "pay the freight," not only with the life blood of its individual members, but in loss of time and money.

From a cold business point of view, it is not profitable to life insurance companies to collect an excess for deaths that ought not to occur, but do and will as long as the present conditions exist, as it is inevitable that it must be paid out. The longer a policyholder lives the more he pays; also the fewer the deaths the greater the profit to the companies; so it can readily be reckoned that the companies are eager for this much-needed reform. It is a notable fact that a few companies refuse to enter the Southern States; others enter, but restrict their operations to certain districts. Evidently there is a reason, and it is not an imaginary one, but is based upon mortality experience tables.

An awakening, Florence says, may be expected when sanitation and hygiene are taught daily in the schools, when sane health laws are passed and consistently enforced, and when the vast financial saving of such procedure dawns upon the average man,—but not till then. It is a well-known fact that when you prove to the average citizen that his pocketbook suffers by any neglect upon the part of himself, or his State, there is found an early remedy; and if we wish to accomplish much we must make that the basis of our plea. The initiation of this sanitary reform, so earnestly desired by the insurance companies, as a purely business matter, depends largely upon the medical profession working through the organized medical bodies; they should by precept and example, in season and out, educate the people, give publicity to these needed reforms, deliver public addresses, and give their expressions to the secular press in no uncertain terms.

Insanity Following Withdrawal of Pension.—Räuber tells of a woman who received a pension because of an alleged carcinoma of the breast. Several years later the pension was withdrawn because the woman was declared to be able to do work. This was followed by an acute outbreak of mental disease, characterized by violence, excitability, and hysterical manifestations. A new application for pension because of this was proposed and Räuber was appointed to decide the matter. The family history showed that there were highly nervous relatives. The patient's behavior during examinations showed abnormality, loss of self-control, tendency to ideas of persecution, etc. The pension was accordingly granted again.—*Zeitschrift für Versicherungsmedizin*, February, 1911.

German Association for the Study of Insurance.—Meltzing reports the proceedings of the medical section of this society at a meeting held December 5, 1910. Ruge spoke of the value of a careful history in cases of alleged accident. Ruge thinks that a history of the circumstances surrounding an alleged accident should always be sufficient to prove whether an accident has really taken place. Cerebral hemorrhages frequently are reported as "accidents" if the patient happens to slide to the floor from a chair, or fall down because of the apoplexy. Appendicitis alleged to be caused by an injury is usually of long standing; the surgical report of the operation gives the necessary data in such a case. Tuberculosis following injury is rare and usually begins at the site of injury. Infections should be included as accidents, if the insured can show that he has taken all proper precautions against them.—*Zeitschrift für Versicherungsmedizin*, February, 1911.

Vital Statistics Among Railroad Employees in Prussia, Hessen, and Alsace-Lorraine.—Eisenstadt contributes a statistical study of the longevity, causes of death, diseases, etc., among railroad employees. The article is not adapted for abstraction.—*Zeitschrift für Versicherungsmedizin*, January, 1911.

Decrease in Railroad Accidents.—A considerable falling off of casualties on interstate railways during the quarter ended March 31 last is shown in the Accident Bulletin for that period issued recently by the Interstate Commerce Commission. There were 2,124 persons killed and 16,430 injured during the quarter, including 706 employees killed and 10,974 injured. This is a decrease of 229 in the number killed and of 2,908 in the injured, as compared with the corresponding quarter of last year. Accidents reported by the electric lines, on which interstate traffic is carried, show that 61 persons were killed and 696 injured during the second quarter, a decrease of 53 in the number killed and 335 in the number injured, as compared with the corresponding quarter of last year.

Book Reviews.

La Base de toute Réforme. Santé, richesse, et liberté assurées à la société et à chaque individu par l'alimentation rationelle. Par Otto Carqué. Libraire de culture humaine: Bruxelles, Belgique.

The mental and moral reform of the human race is to be accomplished, according to our author, by a vegetable diet. Here we meet again our old friends, Chittenden, on the Physiological Economy in Nutrition, and that name which is now in every dictionary, Fletcher. The author even suggests that a vegetable diet will cause a suffragette to regard the ballot as an undesirable possession.

The Practical Medicine Series, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School; and Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Volume II, General Surgery. Edited by John B. Murphy, A.M., M.D., LL.D., Professor of Surgery in the Northwestern University, Attending Surgeon and Chief of Staff of Mercy Hospital, Wesley Hospital, St. Joseph's Hospital, and Columbus Hospital, Consulting Surgeon to Cook County Hospital and Alexian Brothers Hospital, Chicago, Ill. Series 1911. Price $2.00. Chicago: The Year Book Publishers, 1911.

We always review with a great deal of pleasure the books of the Practical Medicine Series, and especially the one on General Surgery. Dr. Murphy not only gives us the meat of the surgical literature of the previous year but he adds to the value of the book by inserting here and there his own opinions and experiences.

War on the Great White Plague. By Rev. John Ischoll.

This small pamphlet is devoted to hygiene and contains also references to the tubercle bacillus, as regards its history, methods of growth, its means of entrance into the human body, and the subjective and objective symptoms that are first noted by the patient. The pamphlet, which is intended for the instruction of the laity, is written in the simplest style. With others of its kind it will doubtless be useful in the fight against tuberculosis.

Diseases of the Joints and Spine. By Howard Marsh, M.A., M.C., Cantab., F.R.C.S., Master of Downing College and Professor of Surgery in the University of Cambridge; Consulting Surgeon to St. Bartholomew's Hospital and to the Hospital for Sick Children, Great Ormond Street; Corresponding Member of the Orthopedic Association, New York. New and Enlarged Edition, thoroughly revised by the Author and by C. Gordon Watson, F.R.C.S., Surgeon to the Metropolitan Hospital; Assistant Surgeon to St. Bartholomew's Hospital and to St. Mark's Hospital for Fistula. With four colored illustrations and eight black and white plates, and upward of 100 illustrations in the text. Chicago: Chicago Medical Book Company, 1910.

This new edition of Marsh's well known and classical work on the Joints contains four new chapters, on Arthritis in Specific Infective Diseases, Septic Arthritis, Intermittent Hydrarthrosis, and Coxa Vara. The chapter on Osteoarthritis has been largely rewritten, and now appears under the title of Arthritis Deformans; it embraces Rheumatoid Arthritis, Osteoarthritis, and Hypertrophic Osteoarthropathy. The use of radiography and vaccine therapy in the diagnosis and treatment of diseases of the joints has necessitated some revision in the other chapters. To make room for this large amount of new material some of the case-narratives have been omitted, and so the size of the volume is not materially greater than before. The work still represents very largely the personal experience of the author; those who are acquainted with the previous editions will need nothing beyond a notice of this third edition; to those who do not know the work it is very cordially recommended.

The Modern Materia Medica, Second Edition, revised and enlarged. Price $1.25. New York: The Druggists' Circular, 1911.

As is aptly stated in the preface to the first edition of this volume, "it is practically impossible for the pharmacist of to-day to keep pace with the developments in modern chemistry as regards new remedies. Hundreds and hundreds of new therapeutic agents are introduced yearly, some meritorious and of permanent interest, others of but passing importance." Likewise, it is practically an impossibility for the physician to keep himself informed on the new agents. Yet at times, in response to the questions of patients about this or that wonderful new remedy, he must be able to obtain reliable information quickly. The Modern Materia Medica meets this need. The list of drugs given is arranged alphabetically for easy reference, and the descriptions furnish all the necessary data regarding each preparation, including the name of the manufacturer.

International Clinics. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, U.S.A. Volume IV. Twentieth Series, 1910. Philadelphia and London: J. B. Lippincott Company, 1910.

This volume contains twenty-six papers, most of them of some value. The first section deals with Diagnosis and Treatment, and contains two articles on "606," a few lines on the United States Pharmacopœia (of no particular value and certainly with no relation to "clinics," international or otherwise), and a magnificent article by L. F. Barker on The Methods of Examining the Blood, of greatest importance for the general practitioner; this last is of considerable value and is quite the most satisfactory article in the volume. The section on Medicine contains three papers; that on Surgery, ten, of which special mention may be made of the contributions of Eisendrath (on the retrocecal appendix) and Ochsner (on colectomy, goiter, appendicitis, etc.). There are two papers on Neurology; one (by Warthin) on Pathology; one on Ophthalmology; two on State Medicine, and one on a so-called Postgraduate Course.

Introduction to Practical Organic Chemistry. Including Qualitative and Quantitative Analysis and Preparations. With a special appendix on the London University syllabus, and schemes of analysis for Stages 1 and 2 of the Board of Education Syllabus. By A. M. Kellas, B.Sc. (Lond.), Ph.D. (Heidelberg), Lecturer on Chemistry at the Middlesex Hospital Medical School, formerly Examiner in Chemistry to the Conjoint Board of the Royal Colleges of Physicians and Surgeons. Price $1.35. London: Henry Frowde, and Hodder & Stoughton, 1910.

This seems to be a very systematic and useful little volume on a subject that does not receive as much recognition as it might in the modern medical curriculum. The preparations are arranged in the order in which they are studied in the theoretical part of the subject, and the general reactions are indicated very clearly; so that the general principles of the science are kept prominently before the student. The book is divided into six parts: 1. Qualitative analysis of organic compounds for elements; 2. General laboratory operations with determination of physical constants; 3. Preparation of typical organic compounds; 4. Tests and analysis for specific compounds; 5. Detection of the group to which a compound belongs; and 6. Quantitative analysis. The book is well printed and well arranged, and is a useful addition to the works on this subject. There is one drawback to the general use of the volume, namely, its binding will not permit of its remaining open at any given page; and as this is so essential for all books used in laboratory work, the absence of this feature is of some importance.

Der Haftapparat der Weiblichen Genitalien, eine anatomische Studie. By Dr. Eduard Martin, Assistant of the Univ.-Frauenklinik of Berlin. With 16 plates. Berlin: S. Karger, 1911. Price $3.00.

This elaborate monograph presents an extended anatomical study of the structures which serve to suspend and attach the female genital organs. The author's aim is to establish more completely in dissections those conditions which are met with in the operative treatment of genital prolapse. The first portion of the work is concerned with the connective tissue, the fasciæ, and the musculature of the pelvic organs. A study of the extensive literature, which serves as an introduction, shows that some uncertainty still exists as to the exact relations of these structures. The dissections are next described and illustrated in a series of 16 well executed folio plates. Among the author's conclusions attention may be particularly directed to the statement regarding the function of the round ligament of the uterus, which, it is claimed, is only brought into action near the end of pregnancy, when it serves to steady the attachment of the lower uterine segment and to anchor the fundus, as with two strong cords, to the bony pelvis. It is also claimed that the labor pains which begin at the fundal portion of the uterus are aided by the resultant fixation of the latter through the round ligaments and that the expulsive action is thus favored. The excellent plates and their careful descriptions are well worthy of study by the obstetrician and gynecologist.

A Handbook of Obstetric Nursing for Nurses, Students, and Mothers. Comprising the course of Instruction in Obstetric Nursing Given to the Pupils of the Training School for Nurses Connected with the Woman's Hospital of Philadelphia. By Anna M. Fullerton, M.D., Formerly Obstetrician, Gynecologist, and Surgeon to the Woman's Hospital of Philadelphia, Physician in Charge and Superintendent of the Nurse School; and Clinical Professor of Gynecology in the Woman's Medical College of Pennsylvania, etc. Seventh revised edition, illustrated. Price $1.00. Philadelphia: P. Blakiston's Son & Co., 1911.

This seventh edition contains two new chapters, one on Examination During Pregnancy and one on Obstetric Operations. The chapters on Care of the New-Born Infant, Eclampsia, Ophthalmia Neonatorum, and Care of Premature Infants have ben enlarged, an dthe book as a whole has been thoroughly revised. The volume is small, but it contains all that is required; and the author's method of treating her subject leaves nothing to be desired. Physicians often want such a book as this for their nurses and the present volume is one of the most satisfactory with which we are acquainted.

State Board Questions and Answers. By R. Max Goepp, M.D., Professor of Clinical Medicine at the Philadelphia Polyclinic; Assistant Visiting Physician to the Philadelphia General Hospital; Associate in Clinical Medicine, Jefferson Medical College. Second edition, thoroughly revised. Price $4.00. Philadelphia and London: W. B. Saunders Company, 1911.

This second edition is little, if any, better than the first. The questions are still only "selected" and are therefore of but little value to any one preparing for a State Board examination. Perchance the questions that the compiler of this bulky volume has omitted are the very ones that some candidate might like to have answered, or might be delighted to omit in his examination if only he might. The statement that this edition is "thoroughly revised" does not appear to be correct, since we find many of the blunders of the former edition perpetuated here. For example: A poison is still defined as "any substance producing deleterious effects upon the animal organism"; this would include an automobile or a stiletto. "Expired air contains no oxygen or only a very little." Na_2CO_3 is given as the formula for sodium bicarbonate. Several of the chemical equations do not balance. The rate of the blood current in the capillaries is given as two inches a second. "Boron is one of the constituent elements of the human body." All of these are reproduced from the first edition, and it would be interesting to know how a State Board examiner would grade these answers. Many of the answers are satisfactory and quite a number appear to have been taken bodily from other sources (*e.g.* from the Medical Record). The value of a work of this sort depends upon its accuracy and not upon its size; and the only students who could use this work with safety are those who do not require such assistance.

The Blues (Splanchnic Neurasthenia). Causes and Cure. By Albert Abrams, A.M., M.D. (Heidelberg), F.R.M.S.; Consulting Physician Denver National Hospital for Consumptives, the Mount Zion and the French Hospitals, San Francisco; President of the Emanuel Sisterhood Polyclinic; Formerly Professor of Pathology and Director of the Medical Clinic, Cooper Medical College, San Francisco. Illustrated. Fourth Edition, Revised and Enlarged. New York: E. B. Treat & Co., 1911.

That this little book has already gone through three editions is sufficient proof of its usefulness and popularity. Dr. Abrams refers to that condition of depression of a paroxysmal nature and of a varying duration known as "the blues" and designates it by the name of splanchnic neurasthenia. Since the apearance of the first edition several additions have been made and in the fourth edition the new feature is note 20 of the appendix, which deals with augmenting the tone of the splanchnic circulation. The "blues" is a very common complaint and therefore a book which claims to recommend successful methods of treatment cannot fail to have readers.

Text-Books of Massage. By L. L. Despard, Member and Examiner, Incorporated Society of Trained Masseuses. Price $4.00. London: Henry Frowde, Oxford University Press; and Hodder & Stoughton, 1911.

The author's aim in writing this textbook has been to embody in concise form such a knowledge of the theory of massage, as well as the principles of elementary anatomy and physiology, as is indispensable to all those desirous of taking up massage as a profession. This book cannot take the place of practical instruction from a competent teacher, for massage is an art that can be mastered only by experience. Nevertheless the successful practice of this art requires an accurate knowledge of physiology and anatomy, of the theory of massage and of its therapeutic indications. Part I takes up the subject of anatomy and physiology. Part II deals with the theory of massage. The first part is replete with excellent illustrations of anatomy, many of which are colored. The descriptions of the various forms of massage, such as stroking (*effleurage*), friction, kneading (*pétrissage*), percussion (*tapotement*) and vibration, are illustrated with many photographic reproductions. The numerous pathological conditions in which massage may be of service are briefly described, and the technique of massage in each case is presented in great detail.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. March 1, 1911. Price $6.00 per annum. Philadelphia and New York: Lea & Febiger.

The present number contains five complete sections. First, sixty pages on Surgery of the Head, Neck, and Thorax, by C. H. Frazier. Second, one hundred and thirty-four pages on Infectious Diseases, including acute rheumatism, croupous pneumonia, and influenza, by J. Ruhrah. Third, Diseases of Children, by F. M. Crandall. Fourth, Rhinology and Laryngology, by D. B. Kyle. And Otology, by A. B. Duel. As is customary, the articles are complete, authoritative, and up to date; the whole makes interesting reading, keeps one well posted with the advance of medical science, and may be said to form an admirable post-graduate course.

Handbook of the Surgery of the Kidneys. By W. Bruce Clarke, M.A., M.B. (Oxon.), F.R.C.S., Senior Surgeon St. Bartholomew's Hospital; formerly Surgeon to the West London Hospital and to St. Peter's Hospital for Stone and other Diseases of the Urinary Tract; Member of the Council and of the Court of Examiners of the Royal College of Surgeons of England; formerly Examiner in Surgery to the University of Oxford. With 5 plates and 50 illustrations in the text. London: Henry Frowde, Oxford University Press, 1911.

This brief work presents a concise account of those lesions of the kidney that are amenable to surgical treatment. The author is well known in England for his work and the book is therefore interesting as presenting his personal views on many topics. There is no attempt made to give the book an encyclopedic chcaracter; it is presented rather as a concise handbook on the subject. The book is well made and the illustrations, mostly photographs from pathological specimens, are appropriate and very satisfactory. After the preliminary chapters on the anatomy of the kidney and ureter, the operations on these organs are discussed, followed by a description of injuries, movable kidney, hydronephrosis, calculus, tubercular disease, pyelonephritis, and other infective conditions and tumors. The general features of each of these are considered, the author frequently making use of the recital of illustrative cases. In reading the book one is impressed that in its less than 200 pages a very satisfactory presentation of this important subject is given.

Collected Papers by the Staff of St. Mary's Hospital, Rochester, Minn., 1905-1909. Philadelphia and London: W. B. Saunders Co., 1911. Cloth, $5.50 net.

This work is presented by the authors as an indexed collection of reprints of articles published by them in recent current medical literature. The medical profession will be a gainer by the fact that this book has been placed on the market instead of being limited to private distribution as was first intended. The work herewith noted comprises articles on the surgery of the alimentary canal, the genitourinary organs, the ductless glands, the head and extremities, and hernia. In addition there are a number of papers on technique and several addresses. There is also a review by Magaw of 14,000 surgical anesthesias, in which attention is centered on the simplicity of the method employed. As all of these papers have already been noted in the current medical periodicals during the last few years, detailed mention of their contents would be out of place at this point, but a final word of praise may be given to the editor for the thorough and satisfactory manner in which these valuable contributions to the literature have been presented for ready reference.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-ninth Annual Meeting, Held in Birmingham, July 25-29, 1911.

(Special report to the MEDICAL RECORD.)

(*Continued from page 402.*)

SECTION OF OBSTETRICS AND GYNECOLOGY.

First Day—Wednesday, July 26.

President's Address.—Professor EDWARD MALIUS of Birmingham in opening the proceedings of the section said that there was still much work to be done in diminishing puerperal mortality and morbidity. Puerperal morbidity was responsible for one-third of all the cases of diseases of women presenting themselves for treatment at the hospital. There had been a great development in the operations of the Central Midwives Board. The roll now contained 31,600 names, of which 10,400 were placed on the roll by examination and 10,000 were accepted on the strength of certificates obtained from other examining bodies before the act came into force; the remainder were of the old type who were registered as having been in practice as "bonafide midwives" before the passing of the act. Two thousand three hundred women passed the examination of the Central Midwives Board each year, and of these 55 per cent. announced their intention to practise. The certificate of the board was much sought after; it was required for many posts as matron of hospitals and for appointments under government. The more efficient training would undoubtedly tend to reduce sepsis, and he thought that especial importance should attach to the teaching of the proper way of taking and recording pulse and temperature. The speaker advocated strongly the establishment of municipal maternity homes, and instanced St. Petersburg, where there were fifteen of these homes, and in these 19,000 cases of midwifery were attended last year, and 41 per cent. of all the confinements in St. Petersburg took place in these homes.

Eclampsia Occurring in Labor in a Girl Aged Twelve—Recovery of Mother and Child.—Dr. C. HUBERT ROBERTS of London read this paper. The child was a Jewess, 4 feet 11 inches in height, and well developed for her age. When first seen she was pallid and edematous, and suffering from mental excitement. The urine contained two-thirds of a column of albumin. The os was the size of a shilling, and the membranes were intact. There was a purulent vaginal discharge. Chloral and potassium bromide, 20 grains of each, were given. Fourteen hours later a fit occurred. The patient was then treated by morphine hypodermically, gr. ⅓, rectal salines, and the hot pack. Four hours later, after a second fit, the child was delivered by forceps. It weighed 7 pounds, and survived. Fourteen convulsions followed the confinement, and these were treated by morphine, gr. 1/16, digitalin, gr. 1/100, and inhalations of chloroform. There was no record of a case of eclampsia at such an early age. The speaker's usual treatment of eclampsia was chloroform, purgation, diaphoresis, saline infusion, and, in certain cases, venesection. Washing out the stomach under anesthesia was also very useful.

Dr. THOMAS WILSON of Birmingham said that the more one saw of these cases the less confident one felt in giving a prognosis. He thought that the preliminary examination of the urine would by no means always show the danger, and in many cases all of the symptoms came on within forty-eight hours.

Prof. HERBERT SPENCER had come to the conclusion that one could not prognose as to which cases would prove fatal. He thought that the urine more often gave warning than the last speaker had stated. He doubted the value of saline infusions.

Dr. HELLIER of Leeds said that in cases in which there were fits and no signs of labor he would rupture the membranes to bring on labor.

Dr. JOHN CAMPBELL of Belfast advised giving morphine, rupturing the membranes, and leaving the case alone, repeating the morphine if there were more convulsions.

Professor STRASSMANN of Berlin said that cases differed at different times of the year, and were generally worse in the cold weather, owing to the effects of cold and wet on the kidneys. Vaginal cesarean section was sometimes useful for this condition, but could be done only in hospital.

Pathology and Treatment of Asphyxia Neonatorum.—Sir FRANCIS CHAMPNEYS of London opened the discussion. He discussed first of all the predisposing causes of the first breath, one of which was the shrinking of the placental site, and later separation of the placenta. The child might not breathe when first born, but if the cord was beating regularly no anxiety need be felt, as the child was still respiring by the placenta. The exciting cause of the first breath was contact with the cold air. There were two varieties of asphyxia: (1) apoplectic or livid blue: (2) syncopal or white, pale, flabby. The second form occurred more often in head-last cases. If the head in these cases was not delivered in three or four minutes the child generally died. The first breath might draw foreign matters into the throat or lungs. As to the question of prognosis and treatment, in a general way it might be said that the blue cases nearly all recovered and the pale ones frequently died. The blue case might be left alone after cleaning out the mouth. In the pale cases the reflexes were lost and the pupils widely dilated. It was no good to allow blood to flow from the cord in such cases. The child should be laid on the back, the mouth wiped out, and the throat gently pressed. A catheter might be passed into the larynx. It should pass down 3½ inches from the lips in order to reach the glottis, and after it was placed *in situ* it should be blown down, and not sucked up. The catheter could then be secured by an elastic band. In doing artificial respiration pressure on thorax was good in adults but bad in new-born children. The only good method of artificial respiration was that known as Sylvester's. In performing it it was important to attend carefully to the following points: The arms should be everted and held above the elbows. In performing Schultze's method the important point was that the whole body of the child should be supported by the fingers under the armpits and that the chest should on no account be grasped. In doing mouth-to-mouth inflation the physician should blow through a cloth, and the nose should not be held. By the first precaution the danger of transmitting tuberculosis to the child was avoided and by the second the possibility of rupturing the lungs. The method of rhythmical traction on the tongue known as Laborde's was worthy of trial. To sum up, he would advise that the physician should never hurry. Before commencing treatment he should endeavor to diagnose the cause of the asphyxia. If the heart was beating ever so slowly the child was not dead, though slowness of heart beat showed a more dangerous state than feebleness. Whatever method was adopted it should not be discontinued until the child breathed regularly.

Dr. HERBERT SPENCER of London said that the pale cases were frequently not asphyxiated at all, but were suffering from shock due to injuries to viscera and internal hemorrhages. To intubate the larynx he used a No. 6 catheter and gripped the larynx externally between the finger and thumb. He thought that Schultze's method sometimes severely injured children by causing hemorrhages into the lungs, and he had proved this by post-mortem examina-

tions on the still-born child. He had had very good results from administering oxygen.

Dr. Hellier of Leeds said that in Sylvester's method we must have the feet held.

Dr. Thomas Wilson of Birmingham said that the first movement should be one of expiration, to get rid of foreign matter. Sylvester's method was the one most taught in this country because it was easier to learn than Schultze's, the latter method being badly taught even in textbooks. Inflation was much inferior to artificial respiration because it did not stimulate the heart. For pale asphyxia he advocated warm baths, and he gave as a criterion for diagnosis between pale and blue asphyxia the following: If the finger was grasped by the child when introduced into its mouth the condition was blue asphyxia; if not, pale.

Dr. Hubert Roberts of London had noticed that babies born after cesarean section looked well at first but later became pale, and he asked the reason. He laid stress on the value of the hot bath in pale asphyxia and said that in these cases a cold bath was absolutely fatal.

Dr. Buist of Dundee described his own method of artificial respiration. He held the child first prone and then supine in each hand alternately. It was an advantage to begin by making a single insufflation. The objection to Laborde's method was that it left the tongue sore and unfit for sucking.

Sir Francis Champneys, in closing the discussion, said that in passing the catheter he passed the little finger down the pharynx, so as to plug the œsophagus, and then passed the catheter with a stylet. He would not teach Schultze's method to midwives. He had found good from placing the child in hot and cold baths alternately.

Second Day—Thursday, July 27.

The Present Position of Vaginal Operations in Relation to the Uterus and Its Adnexa.—Professor Paul Strassmann of Berlin in opening this discussion said that he would reserve laparotomy mainly for large myomata and pus tubes. The dangers of laparotomy were peritonitis, disturbances of intestinal activity, adhesions leading to stomach trouble, and hernia. Great care should be taken to place the omentum in its proper position. Stomach troubles after laparotomy were frequently due to traction from omental adhesions. All stumps should be covered with peritoneum. Unabsorbable ligatures should never be used. Hernia of the abdominal wall had decreased since suturing the fascia separately had been adopted. Laparotomy was the only procedure advisable in many cases, including those where appendicitis might be present, and in cases of tumors of doubtful character. The size of a tumor was not a contraindication, but its character was. For retroflexion he would always operate by the vaginal route. The objections to the vaginal route were: (1) narrowness of the space available; (2) danger of injury to bladder and ureters. The anterior vaginal incision involved more skill than the posterior, but was better for displacements. He described some points in the technique of the anterior vaginal incision. It must not involve the cervix; after opening the peritoneum the cervix was allowed to fall back. He used special forceps for holding the omentum, and said that ordinary artery forceps should not be used for that purpose. After completing the vaginal incisions he removed all specula and inserted the half hand. Conservative operations on the adnexa might be done by this method, and for treating simple adhesions it was much to be preferred to laparotomy, as the latter was too severe. It was also a good operation for pus in the pelvis and for suppurating hematoma. He had given up the use of clamps. In the after-treatment the catheter was sometimes required, but for one day only in most cases. He had found that three-fourths of the women passed water spontaneously on the second day. The exploratory vaginal incision was very good in malignant ascites and to be preferred to laparotomy. In prolapse he thought that one was never justified in opening the abdomen. In the treatment of this condition he had no faith in the Alexander operation, preferring vaginal fixation. He did not do the Schauta-Wertheim interposition operation, however, during the period of sexual activity. He used the vaginal operation for all cases of cancer of the body of the uterus and for cases of cancer of the cervix in fat women. One-half of the cases of ovarian tumors might be dealt with by posterior vaginal incision. Fibroids, when multiple and situated low down on the uterus, could be dealt with vaginally. In 109 cases of extrauterine gestation he had operated on 10 by the abdominal and 99 by the vaginal route, with one death. In anemic women he advised spinal anesthesia, the injection being given with the patient in the lateral position.

Professor Spencer of London did not think that in abdominal section drainage of the wound was always followed by hernia. He thought that there was a danger of tetanus in using catgut. He had found that there was difficulty in controlling hemorrhage in vaginal hysterectomy. He allowed gauze to remain in until the eighth or tenth day.

Dr. Amand Routh of London disagreed as to the better view obtainable by vaginal section, though he allowed that the vaginal operation was not followed by intestinal paresis. He would not attempt to remove fibroids larger than a fist by the vaginal route. He thought that the cystitis following vaginal operations was often due to the use of gauze, and he took the gauze out gradually, beginning two or three days after the operation and removing a fresh piece each day.

Dr. Heller of Leeds said that increasing experience led him to prefer the abdominal route. He advocated removing ovarian tumors entire. He had found that there was more bleeding after the vaginal section, usually taking the form of a troublesome oozing.

Dr. Purslow of Birmingham said he did not believe that knots could be tied as securely in catgut as in silk. Although on the whole he preferred laparotomy there was one condition in which a vaginal incision might save life when an abdominal section would prove fatal; this was in cases of what he might call "acute pus collection in the pelvis," and in these vaginal section was indicated as the immediate treatment, though abdominal section for removal of the pus sac might be required after the acute symptoms had subsided.

Dr. A. W. Russell of Glasgow agreed as to the difficulty of tying secure knots in catgut. He never left gauze in more than twenty-four hours. He used Prior's removable clamps, but found the removal painful and sometimes requiring a little anesthetic.

Dr. Thomas Wilson of Birmingham had occasionally met with dangerous bleeding from the upper part of the pedicle in doing vaginal hysterectomy, and had been compelled to open the abdomen to check this by securing the ovarian vessels. In his fibroid cases he had operated on 35 per cent. by the vagina and had found the mortality of the vaginal and abdominal operations equal. In cancer cases he had had 70 vaginal operations with 1 death, and 50 abdominal (including Wertheim's operation), with 8 deaths.

Dr. John Campbell of Belfast said that in cases of doubt he always used the abdominal method, and he removed ovarian tumors entire. For backward displacements and prolapse he always used abdominal methods, as he had found that the vaginal operations were often followed by relapse.

Mr. Stanmore Bishop of Manchester used silk in the

abdominal cavity and catgut outside. He thought that much of the cystitis met with was due to the catheter, and he strongly opposed the routine practice of passing a catheter before operation.

Dr. Scott Carmichael of Edinburgh said that he considered ventral fixation was never justifiable for retroflexion during sexual life. In mild cases of adnexal disease he would use the vaginal route. For all ovarian neoplasms he would operate by the abdomen.

Dr. May Thorne of London, on the whole, preferred the abdominal route, and was not afraid of hernia even after using a drainage tube. She strongly urged the use of linen ligatures for all purposes.

Mr. R. J. Johnstone of Belfast said that for almost all cases of acute inflammatory disease of the appendages he would prefer the vaginal route. Also for nearly all cases of extrauterine gestation. For tumors and cancer he used the abdominal route.

Dr. Gemmell of Liverpool always used catgut, and had never seen secondary hemorrhage from slipping of the ligature.

Dr. Handfield Jones of London said that some years ago there was a wave of opinion in favor of vaginal operations, and many serious accidents occurred, such as tearing of the bowel. In acute cases of pus formation he advocated vaginal drainage, even if abdominal section was required later.

Third Day—Friday, July 28.

Cause and Cure of Eclampsia.—Dr. Hastings Tweedy of Dublin read this paper. He said that for the purposes of the paper he had not included any case in which albuminuria was not present, and, on the other hand, he had included all cases of toxemic women with albuminuria, even though fits were absent, as he considered that these cases ought to be considered as eclamptic. He had found that any food in the stomach increased the eclampsia. He at first gave milk in these cases when the patient was conscious and could swallow, but he was now strongly of opinion that food in any form, even milk, might be an exciting cause of convulsions. That this was not owing to decomposition of the milk was proved by the fact that even whey produced the same effect. He thought that the milk particles entered the blood and acted as anaphylactic poisons. Pregnancy was a predisposing cause of the condition, and observation showed that pregnant women did not drink enough fluid. He had treated twenty-nine consecutive cases in two years, with no mortality. He withheld all food for some time after the fits had ceased. He had found inhalation of oxygen very useful. He washed out the stomach, but did not leave any fluid in its cavity. The urine was drawn off by catheter. With the patient on the side, the rectum was washed out with sodium bicarbonate solution, one pint at a time, repeated, if necessary, until a gallon or more had been used. He left 1½ pints of this solution in the rectum. If the urine was scanty he gave a subcutaneous injection of the same solution. He had abandoned sodium chloride solution for sodium carbonate. He applied poultice to the loins. He wiped out the mouth with moist cotton wool and discountenanced wiping out the pharynx and the use of a gag. The speaker then dwelt on the importance of having specially trained nurses, and a medical man should always be present during the time the patient was comatose. The head and shoulders must be brought over the side of the bed and the face turned toward the floor. The patient should be disturbed as little as possible, the catheter should be passed every eight hours. He gave morphine hypodermically, beginning with ½ grain, and repeating in ¼-grain doses up to a total of 2 grains. If the respiration fell to 7 or 8 per minute that was an indication that enough morphia had been given. He discountenanced *accouchement forcé*, although when the os was fully dilated forceps might be used, but in most of his cases labor terminated without assistance. The speaker thought that vapor baths did harm, and that chloroform increased the toxemia. Stroganoff advised inhalation of 15 to 20 minims of chloroform for each manipulation required, as catheter, enema, etc., and the speaker intended to try this.

The Dangers of Fibromyomata of the Uterus in the Later Years of Life.—Dr. Nigel Stark of Glasgow read this paper. He said that the only cases in which operation was contraindicated were those of young childless women, when the tumor was producing no symptoms. In all other cases he would operate, and he would never advise delay in operation in the hope that a cure would take place at the menopause. Many more women than was usually suspected died from complications in the later years of life. He had done 140 hysterectomies and 40 myomectomies for uterine fibroids. The dangers in the later years of life were: sepsis and necrosis, calcification, cancer of the uterus, and cancer of the bowel. Sepsis and necrosis accounted for two-thirds of the deaths from fibroids after the menopause. Calcification generally occurred in patients over fifty, and might lead secondarily to suppuration and death. Cancer of the uterus and cancer of the bowel resulted from the mechanically irritating effect of the tumor on neighboring intestine. The changes enumerated occurred in 30 per cent. of the cases of fibroids in later life.

Dysmenorrhea Due to Very Small Fibroids.—Dr. Thomas Wilson of Birmingham, in this paper, said that in the worst cases one had to choose between removal of the ovaries or uterus and the formation of a drug habit. He had done the radical operation for dysmenorrhea in eight cases; in four of these there was no sign of disease, in the other four there were very small fibroids present; in three of these he did hysterectomy, and in the fourth he enucleated the fibroid. It was about the size of a pea, 7 mm. in diameter, and was situated at the level of the internal os. Complete relief of the dysmenorrhea followed its removal. He attributed the dysmenorrhea to the action of the fibroid in interfering with the dilatation of the internal os.

Professors Strassmann and Tweedy discussed these papers and advised splitting the uterus from top to bottom after opening the abdomen. If any fibroids were found they could be enucleated, and if not the uterus could be curetted and sutured up again.

Tuberculous Elephantiasis of the Vulva.—Dr. Purslow of Birmingham reported a case of this kind. The whole labia majora, labia minora, mons veneris, and prepuce of the clitoris were removed by operation. The parts removed were shown; also photographs of the case before operation, and of the microscopical sections taken from different parts of the specimen.

A vote of thanks to the President, Professor Malins, concluded the proceedings.

AMERICAN PEDIATRIC SOCIETY.

Twenty-third Annual Meeting, Held at Lake Mohonk, N. Y., May 31-June 1, 1911.

The President, Dr. Henry Dwight Chapin of New York, in the Chair.

(*Continued from page 405.*)

Diabetes Mellitus in a Seven-Month-Old Child.—Dr. P. J. Eaton of Pittsburg reported this case. The child was brought to a physician because the toes were reddened and swollen. It was found that after urination the diapers were sticky and stiffened upon drying. The specific gravity of the urine was 1035 and there was a decided sugar reaction. Three weeks after the first examina-

tion there was a typical reaction for grape sugar; acetone and diacetic acid were present. The saccharometer read over 10 per cent. These examinations had been made in January and February; in May the specific gravity was 1044; no albumin was found but sugar was present. In a review of the literature of the past fifteen years Dr Eaton had found reports of 647 cases of diabetes mellitus occurring in children; among these there were but seven under the age of one year. The question arose as to whether they were true cases or whether the condition was only transitory. Although the speaker's patient had been under observation for more than four months and the symptom complex was fairly complete, the absence of increased thirst and diuresis caused the speaker to refrain from giving an absolutely unfavorable diagnosis.

Dr. Jacobi of New York said that he had noticed in the literature a few cases of about the same age as the one reported. He himself had seen several; usually they died in a short time, even when ten or fifteen years of age. He had seldom seen one live over a year. However, he had seen two boys in the same family, one of five and the other of seven, about ten years ago, both of whom had diabetes mellitus. He had met one of these boys about a year ago and he was a strapping fellow of sixteen or seventeen. Both boys were in good health; the percentage of sugar in their urine was about three per cent. This was encouraging, and they should not give up in these cases.

Dr. P. J. Eaton of Pittsburgh asked for some hint as to the treatment of diabetes mellitus in children.

Dr. Kerley of New York said the boys to which Dr. Jacobi had referred had been his patients almost since birth. They were athletes and on a reasonably strict diet. The sugar sometimes ran as low as 3 per cent. and sometimes as high as 7 per cent. Dr. Kerley said he had seen other cases of this disease in children where the clinical picture was very different.

Dr. Jacobi, in answer to Dr. Eaton's question, said that he had done what he would have done in the case of adults. The drugs he had been using were four—salicylic acid, continued for a long time and used with bicarbonate of soda; arsenic, in larger doses and higher dilution than were usually given; codeine, which was his preference, and atropine in large doses. Atropine was tolerated in much larger doses by children than by adults.

Symposium on Poliomyelitis—The Present Extent and Distribution of the Disease in the United States and Canada.—Dr. Robert W. Morse of Boston made a report on studies made in two hospitals, one, the Children's Hospital in Boston, and the other, the New York Orthopedic Hospital. It was shown that there had been a gradual increase in the number of cases during the past twenty-five years. The first outbreak in the United States occurred in 1894, and during the following eleven years nine small epidemics were reported, the largest occurring in California and the second largest in Massachusetts. The total number of reported cases during these eleven years was 157. In 1907 there was an extensive epidemic in New York City, 2,500 cases having been reported. In 1908 the disease appeared to be quiescent, but in 1909 a large epidemic occurred in various parts of the United States, a total of 2,343 cases being reported. In 1910 a larger number of cases were reported than at any time before, there being 8,700. In summarizing the speaker said that there was no doubt but that the disease had existed for many years. Charts were exhibited which showed the relative frequency of the disease in America and in Europe. Five-sevenths of the cases had occurred in this country. The disease was reportable in but twenty-three States. State boards of health should make it reportable. A careful house-to-house study of poliomyelitis should be made by competent medical men. The solution of the problems connected with this disease might come from the laboratory or from field work. The medical profession should have every facility offered them in order to obtain the information needed; they should have financial support.

Prevailing Clinical Manifestations — The Cerebral Type.—Dr. Henry Koplik of New York said that the cerebral forms of poliomelitis had been brought to the attention of the profession in 1905 and in the epidemic described by Wickman in Sweden. In these cases the membranes of the brain and medulla as well as the brain itself and the medullary substance were involved. With the cerebral symptoms they had nuclear palsies; the muscles of the oculomotor group were frequently involved. There are cases of ophthalmoplegia and of paralysis of the facial muscles with the symptoms of meningitis, giving the picture described by Wernick as polioencephalitis inferior. If the process extended further down and involved the hypoglossal or bulbar muscles there were symptoms of bulbar paralysis added to the cerebral symptoms. In this last group were numbered some of the fatal cases. In some cases all forms might be merged into one another. The greatest difficulties in diagnosis were offered by these cerebral cases which might simulate either meningococcic meningitis with isolated basic palsies or meningitis of the tuberculous type. The speaker described three types: 1. A child, previously in good health, might be attacked with high fever, headache, and vomiting. After about twenty-four hours he went to bed with a tired feeling; there was increasing stupor, and the temperature subsided to normal or a little above. The patient might be delirious, irrational, and hyperesthetic. There were rigidity of the neck, Kernig's sign, and a mild hydrocephalus. After a week the patient became more rational, recognizing objects and friends; or the disturbance might continue with the hydrocephalus. In some cases the temperature was normal and in others it might continue at 102° or 103° F. for a week and then subside to normal. Recovery might take place with a slight strabismus, optic neuritis, and choked disc. These might pass away or there might remain an absolute blindness which improved after a time. There might be an ophthalmoplegia with rigidity of the eye and dilated pupil, which might remain indefinitely. The condition differed from that of acute meningitis in that there was a preliminary period when the patient was up and around. 2. This type resembled the tuberculous form of meningitis, but the onset was sudden. There were fever, high or low; vomiting, and, after a day or two, sopor, normal temperature, and unconsciousness. There were marked hydrocephalus, facial paralysis, ocular palsy, loss of reflexes, no Kernig's sign, Cheyne-Stokes respiration, mild neck rigidity, and no reaction to mechanical or other stimuli in the paralytic stage of the meningitis. The patient might die or recover with hydrocephalus. 3. In this type there was a short period of fever, then normal temperature, stupidity, and a trance-like cataleptic state. The patient then became brighter and presented a motor ataxia, vertigo, and final recovery. It should be differentiated from the tuberculous forms of meningitis by the sudden onset. Dr. Koplik reported eight cases belonging to the above types. The fatal cerebral cases not only included cases of the above forms but those in which there was a picture of an acute bulbar paralysis. The onset might be acute or gradual and the paralysis might involve the muscles of deglutition and phonation as well as of respiration. There might also be a complete motor paralysis which extended down and involved the muscles of the trunk and extremities. In these cases the fluid obtained by lumbar puncture might give a lymphocytic cytology and the blood might show a polymorphonuclear leucocytosis.

Prevailing Clinical Manifestations—The Spinal Type.—Dr. John Lovett Morse of Boston stated that it was commonly known that paralysis came on quickly in the

course of a few hours or at most three or four days; this was followed by a stationary period of from one to four weeks and then the period of improvement set in, lasting six months or perhaps a year. It was impossible in the acute stage to prophesy how extensive the final paralysis would be. The points upon which a prophesy might be based were the character of the initial paralysis, the time of the beginning of the retrogression and the slowness of its progress, and the character of the final paralysis. As a rule, spinal paralysis was mono or hemiplegic, seldom diplegic or paraplegic; and it was comparatively unusual to have all of the muscles of the extremities involved. The grouping of the paralyzed muscles had, moreover, no relation to their physiological function or to their distribution. In a certain number of cases the paralysis was progressive in type, as that of the so-called Landry's paralysis. It was probable that a very considerable number of those cases were really cases of infantile paralysis. In the polyneuritic type pain was a prominent symptom. It was usually most marked in the paralyzed parts. There was a combination of rigidity and resistance only when the muscles were but partially paralyzed and when some of them were intact. Failure to appreciate the significance of this condition led to many errors in diagnosis during the acute stage. The diagnosis after the appearance of paralysis was very easy; the difficulty lay in making a diagnosis before its appearance. Sweating, marked irritability, and hyperesthesia were present in many instances, but they were not constant. Hyperesthesia was the most constant symptom. Leucopenia occurred in animals during the early part of the acute stage of infantile paralysis, but it was not a constant symptom in man. The only possible method of making a diagnosis of infantile paralysis of the spinal form before the onset of paralysis was by lumbar puncture.

The Present Status of Experimental Work Upon the Nature and Treatment of the Disease.—Dr. Simon Flexner of New York said that in dealing with the topic assigned to him he would take cognizance of the fact that they were already familiar with much of the experimental work on this disease. They were aware that infantile paralysis, as it occurred in human beings, was transmissible to monkeys; however, monkeys were only susceptible to the experimental form of the disease. The disease had not yet appeared spontaneously among monkeys as the result of contact; in order to produce the infection it was necessary that the virus should pass the barriers of the external surface of the body. This defense against the infection was not possessed by the human being, especially the young. When a small quantity of the virus was brought to the central nervous system and injury was inflicted then the monkey was more susceptible than the human being, and the mortality was much greater in the monkey than in the human being. The speaker said there were two questions which seemed to him to be of importance in reference to the disease under discussion: First, control by prevention; second, its cure by treatment. In regard to the control of the disease by prevention, any knowledge which related to the manner of infection would lead to the introduction of methods which looked toward prevention. It seemed that direct contact was necessary to bring about a distribution of the disease. Not many instances were known where direct contact had occurred which had been followed by secondary cases. There might be other means besides direct contact which would in time be discovered; at present the human agency was the best to consider. Their discoveries had suggested that some other agency was responsible for the transmission of this disease. They were trying to determine whether or not an insect could be responsible for its transmission. The speaker did not wish to be understood as stating that insects transmitted the disease, but they could be contaminated and be made transmittors of the disease. Poliomyelitis was a disease that affected all classes of society alike and appeared under the best as well as the worst sanitary conditions. The disease was one of the summer time. The house fly fulfilled all the conditions set forth by the speaker. Experiments with the fly showed that when contaminated with the virus of poliomyelitis the fly harbored the virus in a living and infectious state for at least forty-eight hours. The experiments did not show that this was the limit of the period of survival, and they threw no light on the question as to whether the virus was retained merely as a superficial contamination or whether it could survive in the gastro-intestinal tract. Experiments relating to these points were in progress. In considering the second point, the therapy of the disease, Dr. Flexner said that because the disease was sudden in onset and rapid in development and because so much improvement took place after this onset he believed there was hope for a rapid restoration of function. The question of therapy suggested itself along two lines. One was the serum therapy. There was a large variety of animals that could be immunized to a certain extent. The value of the serum was slight, however; it was so weak that it was doubtful if it could ever be applied in the treatment of this disease. He had thought of the addition of some chemical, as urotropin. It had been proven that urotropin had the power of preventing the disease in monkeys. The question arose as to whether it could not be modified in directions looking toward an improved action. It was remarkably easy to add chemical groups to urotropin. They had now quite a series which could be added, perhaps fifteen. These had been used only on monkeys, and the time was ripe to apply them to human beings. These drugs were carried extremely well in the serum as well. It was probably better to use these agents with the serum than to administer them alone. Hitherto all drugs had their effects neutralized by the serum.

The Most Promising Outlook for Improvement in the Treatment from the Standpoint of the Pediatrician.—Dr. J. H. Mason Knox of Baltimore read this paper.

Dr. Samuel S. Adams of Washington related his experience with the management of a Washington hospital because it was thought that he had not been sufficiently careful to isolate cases of poliomyelitis. He had written letters to hospitals all over the country asking questions in regard to the management of this disease and had been surprised to learn that in many they took no precautions against contagion. He had also learned that many physicians did not report cases of poliomyelitis. Five hundred cases had been reported in the District of Columbia, and that was far from the number that really occurred. Dr. Adams was supporting the Marine-Hospital Service in its efforts for compulsory isolation. He could not understand why physicians who were otherwise conscientious were absolutely indifferent to the methods of prevention of this veritable scourge, which had recently so increased its virulence.

Dr. Westcott of Philadelphia said that he had found that lumbar puncture gave relief to the pains in the joints, which were one of the most distressing symptoms of the disease.

Dr. Jacobi described the disease as it looked fifty years ago and as it had appeared to him when he wrote on the subject in 1862. At that time his treatment consisted in the application of ice, now and then a mustard plaster, and tincture of iodine; the administration of a purgative, calomel or saline, and ergot in the beginning. He formerly never used strychnine. Electricity might be relied on to some extent in certain cases. He had found now that strychnine occasionally did some good in older cases. It should be given subcutaneously.

Dr. Cotton of Chicago described the first case that he had diagnosed in its incipiency and said that as he reviewed the history of this disease it occurred to him that

there were many little epidemics which occurred without ever having been reported before the attention of the profession was focused upon the subject. The speaker thought that the rational treatment indicated by the pathology of the disease was one of depletion. Elimination of the toxin was certainly desirable. He suggested catharsis, diaphoresis, diuresis, depletion, and rest; even by blood letting good might be accomplished. He always applied bromide and ergot and would also use atropine. During the past eighteen months he had had three cases which he treated in this way.

Dr. Blackader of Montreal asked Dr. Flexner whether he considered lumbar puncture of value in the treatment of poliomyelitis.

Dr. Floyd Crandall of Philadelphia said he had seen his first case twenty-three years ago, and the cases he saw at that time seemed to resemble the description given by Dr. Jacobi. Later it became difficult for him to readjust his conception of the disease. It seemed that it appeared today in a rather different form from that manifested twenty years ago.

Dr. Morse of Boston said that as he understood the disease there was an obstruction to circulation through the arteries in the cord and, therefore, he failed to see how leeches, bloodletting, purgatives, etc., could have any good effect. In the cases that Dr. Morse had seen seventeen years ago a diagnosis of rheumatism had usually been previously made.

Dr. Acker of Washington mentioned several epidemics of poliomyelitis that had occurred in that city. The one last summer began in June and lasted until September. He had not seen any cases of contagion. On Washington avenue leading out to the country cases occurred along the avenue but not out in the country. He had found that hot baths given during attacks relieved the pain. Where lumbar puncture had been used it seemed to relieve the pain almost immediately.

Dr. Machell of Toronto asked Dr. Flexner whether they had noticed that cases occurring in the last epidemic had been milder than those seen in former years. This seemed to be the case in Toronto. The disease had appeared to occur in younger children, also. Several cases had a rash something like chicken pox.

Dr. Simon Flexner of New York, in answer to Dr. Blackader's question, said that he thought that lumbar puncture could do no harm. As to the question of contagion, poliomyelitis was not contagious as were scarlet fever and measles, but there were plenty of instances where several cases had occurred in the same family. In the present state of their knowledge and ignorance they should consider the disease contagious. As to the persistence of the virus in the nasopharynx, it was present there in the acute stage of the disease and it had been proven to be present in the nasopharynx of the monkey for six months after recovery from the disease. These were probably exceptional occurrences, like the the occasional persistence of the diphtheria bacilli. The speaker was of the opinion that three or four weeks was the limit of contagiousness in the human being. For a local disinfectant he recommended menthol in the usual combination; it led to cleanliness, and he believed that mechanical cleansing was an important factor.

Dr. Koplik of New York said he did not know whether the type of the disease was different from what it formerly was or not. He emphasized the point made by Dr. Flexner that they could not compare hospital cases with those seen in private practice.

Dr. Knox of Baltimore expressed his disapproval of bloodletting, as antibodies were produced in the blood, and to remove the substance in which they were produced was to destroy one of the best means of protection.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Delaware.

June 20-22, 1911.

ANATOMY.

1. Explain formation of skull, giving sutures connecting the individual cranial bones.
2. Explain formation of (infantile) anterior fontanelle.
3. Give origin, insertion, and length of the omohyoid muscle.
4. Origin, insertion, and length of the thyrohyoid muscle.
5. Origin, course, and distribution of subclavian artery.
6. Origin, course, and distribution of the common carotid artery.
7. Origin, course, and distribution of internal jugular vein.
8. Origin, course, and distribution of pneumogastric nerve.
9. The brachial plexus of nerves is how formed? Where distributed?
10. Hair follicles are how formed? How nourished?

PHYSIOLOGY.

1. Define (1) birth, (2) life, (3) death.
2. What are the percentages of O, CO_2, and N in arterial and venous blood respectively?
3. Describe a cardiac cycle.
4. What functions do the lymphatics and lacteals perform?
5. What parts of the digestive processes are performed in the mouth?
6. What functions are performed by the liver?
7. Describe the gaseous interchanges which take place in the lungs during respiration.
8. Name the glands of the skin and describe their functions.
9. How is the normal temperature of the human body maintained in health?
10. Discuss the sympathetic nervous system.

CHEMISTRY.

1. What is a meter, liter, and a gram?
2. Describe specific gravity and evaporation.
3. What are the incompatibles of the iodides and what is the antidote for tr. iodine poisoning?
4. Give symptoms and treatment of corrosive sublimate poisoning.
5. Give symptoms and treatment of nitrate silver poisoning.
6. Define organic and physiological chemistry.
7. What are three of the most important products of the halogen derivatives of methane?
8. What are aldehydes? Name three of the most important compounds.
9. What are benzine hydroxides?
10. What are terpenes and stearoptens? Describe menthol and thymol.

MATERIA MEDICA.

1. What is salol and why should care be exercised in its administration?
2. Name the incompatibles of iron.
3. Give the preparations of opium and tell what proportion of this drug is in paregoric and Dover's powder.
4. Compare the physiological actions of ether and chloroform.
5. Name the chemical antidote of iodine. Arsenic.
6. Give the common name, active principle, preparations, and doses of aconite.
7. Define aphrodisiac (*a*) oxytocic (*b*) emmenagogue. Mention one drug of each class
8. Make a list of the ammonium salts
9. Give the preparations and doses of belladonna.
10. What do we mean by hydragogue diuretics? Name three drugs of this class.

THERAPEUTICS.

1. What is Dr. Young's rule for ascertaining the dose for children?
2. How would you procure and maintain intestinal asepsis?
3. What property or power has diastase?

Describe the therapeutic uses of the following:

4. Ergot. 5. Bismuth. 6. Hydrastis. 7. Arsenic. 8. Ipecac. 9. Sodium chloride. 10. Hydrochloric acid.

PATHOLOGY.

1. Define (1) toxemia, (2) bacteremia
2. Describe the bacillus typhosus.
3. Discuss the theories of immunity.
4. Name the cardinal signs of inflammation.
5. Describe the process of repair in a fractured bone.
6. Describe briefly a miliary tubercle.
7. Give the pathology of cirrhosis of the liver.
8. Describe a kidney from a case of chronic interstitial nephritis.
9. What is the clinical significance of an excess of uric acid in the urine?
10. Give a classification of the carcinomata.

PRACTICE OF MEDICINE.

1. Give etiology and symptoms of arteriosclerosis. At what age does it usually occur?
2. Describe symptoms and treatment of acute laryngitis.
3. Mention the conditions that would contraindicate the use of a general anesthetic.
4. Give symptoms and treatment of exophthalmic goiter.
5. Outline the symptoms and give treatment of tubercular peritonitis.
6. What are the symptoms of mitral incompetency? Differentiate same from purely functional heart murmurs.
7. Differentiate angina pectoris from pseudo-angina.
8. Give the clinical history of chronic catarrhal gastritis.
9. Give period of incubation, symptoms, and treatment of measles.
10. Define and give treatment of acute appendicitis

OBSTETRICS.

1. Define menstruation. Name condition influencing same.
2. Give a summary of the diagnostic signs of pregnancy.
3. Name the most frequent cause of ophthalmia neonatorum. Give treatment, prophylactic and curative.
4. Name every possible source of postpartum hemorrhage and your method of controlling the same.
5. What conditions would indicate the following procedures: (*a*) version, (*b*) high forceps, (*c*) cesarean section?
6. Diagnose placenta prævia. Name varieties and give treatment of each variety.
7. Give rules for calculating the date of confinement. (1) When the date of a single cohabitation is known. (2) When the date of the last menstruation is depended upon. (3) When the date of the last menstruation is unknown.
8. What is the placenta? Describe Crede's method of placental expression.
9. Give the hygienic rules you would consider important for a pregnant woman to observe.
10. Differentiate pregnancy (7-months) from any four other similar conditions.

SURGERY.

1. Give in detail the method for operating for circumcision.
2. Explain the several methods for suppression of hemorrhage.
3. Explain the primary causes of atrophy of bone structures.
4. What structural changes favor hematocele as a sequela of hydrocele?
5. Explain the general rules that should be observed in the reduction of fractures of the arm and forearm.
6. What are the general rules that must be observed in the reduction of dislocation of shoulder and hip joints?
7. What general rules govern the ligation of all large arteries? Give in detail the technique to be observed in operating.
8. In what particular does neurotomy differ from neurectomy?
9. Differentiate dry and suppurative synovitis. In what particular does the treatment differ?
10. Give etiology, diagnosis, and treatment of strumous synovitis.

HYGIENE.

1. Define hygiene, health, and disease.
2. Where and when is the relative humidity of the atmosphere the greatest, and state its influence on health?
3. Give general rules, in full, for ventilation.
4. What are the most reliable sources for pure drinking water, and what are the best methods of purification?
5. What diseases of domestic animals are communicable to man? Give best method of meat inspection, and state the effect of light and dark meats on the human system and what influence they may have on certain diseases.
6. What effect has exercise on the circulation, nervous system, and the elimination of nitrogen?
7. What is the most important feature of quality in summer clothing, hygienically, as a protection against heat?
8. Name six contagious diseases in which no specific organisms have as yet been isolated.
9. What disinfecting methods, measures, and agents would you employ in the exanthemata, respiratory, and intestinal diseases?
10. What comprises vital statistics proper?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF DELAWARE.

June 20-22, 1911.

ANATOMY.

1. Gray's "Anatomy" (1910), pages 123 and 121.
2. Gray's "Anatomy" (1910), page 143.
3. OMOHYOID. *Origin:* Upper border of scapula. *Insertion:* Inferior border of body of hyoid bone.
4. THYROHYOID. *Origin:* Side of thyroid cartilage. *Insertion:* Inferior border of body and greater cornu of hyoid bone.
5. See Cunningham's "Anatomy" (1909), page 821; or Gray's "Anatomy" (1910), page 625.
6. See Cunningham's "Anatomy" (1909), page 801; or Gray's "Anatomy" (1910), page 586.
7. See Cunningham's "Anatomy" (1909), page 875; or Gray's "Anatomy" (1910), page 746.
8. See Cunningham's "Anatomy" (1909), page 690; or Gray's "Anatomy" (1910), page 1006.
9. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius.

And see Cunningham's "Anatomy" (1909), page 622; or Gray's "Anatomy" (1910), page 1029.

10. See Cunningham's "Anatomy" (1909), page 776; or Gray's "Anatomy" (1910), page 1161.

PHYSIOLOGY.

1. *Birth* is the act of being born, or the passage of the child from the uterus to the outside world.

Life is the sum of the properties that enable an organism to adapt itself to surrounding conditions.

Death is the complete and permanent cessation of functional activity.

2. In *arterial blood* there is 20 per cent. of oxygen, 1 to 2 per cent. of nitrogen, and 40 per cent. of carbon dioxide; in *venous blood* there is 8 to 12 per cent. of oxygen, 1 to 2 per cent. of nitrogen, and 46 to 50 per cent. of carbon dioxide.

3. The *cardiac cycle* includes all the changes which occur between the commencement of one heart-beat and the commencement of the next; it consists of the alternate contractions (or systole) and relaxations (or diastole) of the auricles and ventricles of the heart. The contraction of the two auricles takes place simultaneously, and is followed by the simultaneous contraction of the two ventricles; then follows a period during which the whole heart is in a state of diastole. The cycle then begins again with the auricular systole.

4. *Function of lymphatics:* To provide the tissues with material necessary to their functional activity, growth, and repair; to receive from the issues their waste products; and to convey the products of digestion and absorption to the blood-current.

Function of lacteals is the absorption of fats from the small intestine.

5. Mastication, insalivation, and the commencement of the conversion of starches into maltose.

6. *Functions of the liver:* (1) Secretion of bile; (2) formation and storage of glycogen; (3) formation of urea and uric acid; (4) manufacture of heat; and (5) the conversion of poisonous and harmful substances into inert material.

7. Oxygen passes from the air in the lungs, through the alveoli, to the capillary walls, and into the blood plasma, by *diffusion*. Similarly the carbon dioxide passes from the blood to the atmospheric air.

8. The glands of the skin are: (1) SWEAT GLANDS, whose *function* is the secretion of sweat; and (2) SEBACEOUS GLANDS, whose *function* is the secretion of sebum.

9. The normal temperature of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. Heat is *gained* in the body by (1) the muscles, during contraction; (2) the secreting glands; (3) the brain, during mental activity; and (4) by the ingestion of food and hot liquids.

Heat is *lost* to the body by (1) the skin, through evaporation, radiation, and conduction; (2) the lungs; and (3) the excretion (feces and urine).

10. See Cunningham's "Anatomy" (1909), page 703; or Gray's "Anatomy" (1910), page 1066.

Functions: "It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves) are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or less extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*."—(*Reference Handbook of the Medical Sciences.*)

CHEMISTRY.

1. A *meter* is a measure of length, and is a little more than 39 inches.

A *liter* is a measure of capacity, containing 1000 cubic centimeters, or a little more than a quart.

A *gram* is a measure of weight; it is equivalent to about 15½ grains.

2. *Specific gravity* is the weight of a given volume of a substance as compared with the weight of an equal volume of some substance, accepted as a standard of comparison, under like conditions of temperature and pressure.

Evaporation is change from liquid to a gaseous or vapor form.

3. *Incompatibles of the iodides* are: Alkaloids, bromine, chlorine, metallic salts, nitrites in acid solution, and salts of arsenic in acid solution.

The antidote for tincture of iodine poisoning is starch.

4. The *characteristic symptoms of poisoning by corrosive sublimate* are: A burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; bloody stools; also salivation may occcr.

Treatment: The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

5. SILVER NITRATE POISONING. *Symptoms:* Pain; vomiting of white, cheesy matter, which becomes black in the sunlight; cramps, purging, depression; convulsions; coma or collapse. *Antidote:* Solution of sodium chloride.

6. *Organic chemistry* is the chemistry of the carbon compounds.

Physiological chemistry is the chemistry of the living organism and of all its processes.

7. Chloroform (trichlormethane), bromoform (tribromomethane), and iodoform (triiodomethane).

8. Aldehydes are substances intermediate between alcohols and acids; they are the first oxidation products of primary alcohols, and on further oxidation become acids. Formaldehyde, acetaldehyde, and trichloraldehyde (chloral).

9. There are no benzine hydroxides.

10. *Terpenes* are hydrocarbons having the formula $C_{10}H_{16}$.

Stearoptenes are the solid part of a volatile oil; camphors are stearoptenes.

Menthol is a secondary alcohol derived from oil of peppermint; it is a colorless crystal, with odor of peppermint, a warm aromatic taste; freely soluble in alcohol or ether, and but slightly soluble in water.

Thymol is a phenol contained in oil of thyme; it is a colorless crystal, with aromatic odor and pungent taste; soluble in alcohol, ether, fats, and oils, but only sparingly soluble in water.

MATERIA MEDICA.

1. Salol is phenyl salicylate. Care should be exercised in its administration, because large doses may produce phenol poisoning.

2. INCOMPATIBLES OF IRON. "Incompatible with *Metallic Iron* are: Hydrogen dioxide, oxidizers, potassium chlorate, potassium permanganate; salts of antimony, copper, bismuth, lead, mercury, and silver. With *Ferrous Salts* are: Alkalies, carbonates, chromates, chlorates in acid solution, ferrocyanides, gold salts, hydrogen dioxide, mercuric salts, phosphates, permanganates, sulphides, tannic acid, silver salts. With *Ferric Salts* are: Acacia, albumin, alkalies, apomorphine, aloin, benzoates, carbonates, creosote, balsam of Peru, benzoin in alcoholic solution, diuretin, gallic acid, gelatin, guaiac, guaiacol, hydriodic acid, hypophosphites, hyposulphites, iodides, morphine; oils of bay, cloves, cinnamon, pimento, thyme, and wintergreen; pyrogallol, resorcin, salol, salicylates, sulphides, sulphites, tannic acid, vegetable infusions and decoctions.

"Incompatible with the *Tincture of Ferric Chloride* are: Acacia, albumin, alkalies, carbonates, gelatin, lime-water, magnesium carbonate, piperazin, vegetable decoctions infusions, and tinctures. With *Ferrous Sulphate* are: Alkalies, carbonates; chlorides of ammonium, barium, and calcium; gold and silver salts, lead acetate, lime-water, piperazin, potassium iodide, potassium nitrate, Rochelle salt, sodium borate, tannic acid, vegetable astringent infusions." (Potter's *Materia Medica.*)

3. *Preparations of opium:* Pulvis opii, opium granulatum, opium deodoratum, extractum opii, pilulæ opii, tinctura opii, tinctura opii deodorati, vinum opii, acetum opii, tinctura opii camphorata, emplastrum opii, pulvis ipecacuanhæ et opii, tinctura ipecacuanhæ et opii, trochisci glycyrrhizæ et opii.

Paregoric contains 4/10 of 1 per cent. of opium. Dover's powder contains 10 per cent. of opium.

"4. *Ether* is anodyne, antispasmodic, diaphoretic and anthelmintic; a cardiac and cerebral stimulant, an anesthetic, and a narcotic poison. Given internally, it is a most powerful stimulant of secretion, acting especially on the secretions of the stomach, salivary glands, and pancreas. On the cerebrum and the motor and sensory nerves its action is similar to that of alcohol, but more prompt and less protracted. It is eliminated rapidly, chiefly by the lungs.

"The action of *Chloroform* is similar to that of ether, with several important differences. It is more irritant to the mucous membranes, and if swallowed undiluted it produces violent gastroenteritis, which becomes apparent after the subsidence of the profound narcotism which at first follows its ingestion in quantity. A dose of ℥j internally may cause death, though recovery has taken place after the ingestion of one, two, and even three ounces. (Wood). It clots the blood outside the body, converting it into a mass resembling sealing-wax.

"As compared with ether the inhalation of chloroform is less stimulating, more irritant to the kidneys, more depressant to the vital functions, and much more dangerous on account of its direct paralyzant action on the heart. Its vapor is less irritant to the air-passages, non-inflammable, more agreeable, more prompt in action, produces much less subsequent vomiting, a shorter stage of excitement, and a more profound degree of narcosis; and should be diluted with 96½ per cent. of air to produce anesthesia with safety, according to the general teaching on this subject."—(Potter's *Materia Medica.*)

5. The chemical antidote of *iodine* is starch; of *arsenic*, is freshly prepared solution of ferric hydroxide.

6. ACONITE. *Common name*, monk's hood; *active principle*, aconitine; *preparations and doses:* Fluidextract, ♏j; and tincture, ♏x.

7. *Aphrodisiac* is an agent which arouses or increases sexual desire and power; as phosphorus.

Oxytocic is an agent which stimulates contraction of the gravid uterus, and may produce abortion; as ergot.

Emmenagogue is an agent which restores the menstrual functions; as savine.

8. *Ammonium salts:* Benzoate, bromide, carbonate, chloride, iodide, salicylate, and valerate of ammonium.

9. Extract of belladonna leaves, gr. 1/10 to ½; tincture of belladonna leaves, ♏vij; belladonna plaster, belladonna ointment; fluidextract of belladonna root, ♏j; and belladonna liniment.

10. *Hydragogue diuretics* are diuretics which increase the water of the urine considerably; as digitalis, caffeine, and squill.

THERAPEUTICS.

1. *To determine the proper dosage for a child:* Let x = the age of a patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient of

four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

2. It is not possible to procure and maintain intestinal asepsis.

3. Diastase has the power of converting starch into sugar.

4. *Therapeutic uses of ergot:* To promote uterine contractions during third stage of labor; for fibroids, menorrhagia, postpartum hemorrhage; some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

5. *Therapeutic uses of bismuth:* "Bismuth salts, as dusting powders and in ointments, are used for excoriated surfaces, wounds, etc., and in the treatment of skin diseases. The subnitrate, snuffed into the nostrils, is employed in coryza and simple ozena and as a topical application in aphthous or nursing sore mouth, mercurial ptyalism, chronic conjunctivitis, and granular lids, and ulcers of the rectum. Internally bismuth salts are useful in gastralgia, vomiting, gastritis, and diarrhea, and as intestinal antiseptics." (Wilcox's *Materia Medica.*)

6. *Therapeutic uses of hydrastis:* As a stomachic tonic, for catarrh of the gastrointestinal tract, for gonorrhea, gleet, nasal catarrh; as an application to ulcers, sores, hemorrhoids, fissures, etc.; in menorrhagia.

7. *Therapeutic uses of arsenic:* In stomach disorders, bronchial and pulmonary affections, diabetes, diarrhea, anemia and chlorosis, chorea, malaria, and chronic skin diseases.

8. *Therapeutic uses of ipecac:* As an emetic to clear the respiratory passages, to relieve the stomach, in bronchitis, emphysema, dysentery and jaundice, and as a diaphoretic in rheumatism.

9. *Therapeutic uses of sodium chloride:* "Locally it is of service in affections of the mucous membranes, and salt baths are invigorating as well as cleansing. A strong solution constitutes one of the best injections for threadworms, and salt solutions are also used to limit the action of silver nitrate. Hot salt, enclosed in bags, is a good application in lumbago and various other painful conditions. Internally as an emetic and also in dyspeptic conditions, administered in carbon dioxide water or in the form of natural mineral waters. Solutions of salt in distilled water are given by intravenous injection or hypodermoclysis in conditions where the body has lost much fluid and also in carbon dioxide or coal gas poisoning and in uremia and similar intoxications. On poisoning by silver nitrate sodium chloride arrests the corrosive action." (Wilcox's *Materia Medica.*)

10. *Therapeutic uses of hydrochloric acid:* As a caustic; also when the gastric juice is deficient in acidity, in some forms of dyspepsia, and in some fevers (such as typhoid).

PATHOLOGY.

1. *Toxemia* is a condition in which bacterial toxins are present in the blood.

Bacteremia is a condition in which bacteria are present in the blood.

2. *Bacillus typhosus* is a rod-shaped organism, with rounded ends, is from 2 to 4 microns in length, and about three-fourths of a micron in breadth; it does not stain by Gram's method but stains with all the aniln dyes; it has flagella, no spores, is aerobic and facultative anaerobic, and is motile.

3. See French's "Practice of Medicine" (1910), page 00.

4. Redness, swelling, pain, heat, and disordered function.

5. See Rose and Carless' "Surgery" (1908), page 472; or Da Costa's "Surgery" (1908), page 457.

6. See Rose and Carless' "Surgery" (1908), page 166; or Da Costa's "Surgery" (1908), page 213.

7. See French's "Practice of Medicine" (1910), pages 832 and 849; or Osler's "Practice of Medicine" (1909), pages 557 and 561.

8. See French's "Practice of Medicine" (1910), page 925; or Osler's "Practice of Medicine" (1909), page 695.

9. See French's "Practice of Medicine" (1910), page 903; or Osler's "Practice of Medicine" (1909), page 677.

10. See Rose and Carless' "Surgery" (1908), page 209; or Da Costa's "Surgery" (1908), page 333.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), pages 640 and 642; or Osler's "Practice of Medicine" (1909), pages 848 and 851.

2. See French's "Practice of Medicine" (1910), page 660; or Osler's "Practice of Medicine" (1909), page 596.

3. *Contraindications for a general anesthetic* are said to be: Fatty degeneration or dilatation of the heart, disease of the lungs or kidneys, cerebral tumors, and chronic alcoholism; also enlarged tonsils. (Gould and Pyle's *Pocket Cyclopedia.*)

4. See French's "Practice of Medicine" (1910), page 558; or Osler's "Practice of Medicine" (1909), page 706.

5. See French's "Practice of Medicine" (1910), pages 357 and 408.

6. See French's "Practice of Medicine" (1910), page 590; or Osler's "Practice of Medicine" (1909), page 805.

Functional heart murmurs are usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient; and they denote, as a rule, an impoverished condition of the blood.

7. See French's "Practice of Medicine" (1910), page 636; or Osler's "Practice of Medicine" (1909), page 841.

8. See French's "Practice of Medicine" (1910), page 751; or Osler's "Practice of Medicine" (1909), page 461.

9. See French's "Practice of Medicine" (1910), pages 326 and 331; or Osler's "Practice of Medicine" (1909), pages 141 and 145.

10. See French's "Practice of Medicine" (1910), pages 805 and 816; or Osler's "Practice of Medicine" (1909), pages 512 and 518; and Rose and Carless' "Surgery" (1908), page 1045; or Da Costa's "Surgery" (1908), page 861.

OBSTETRICS.

1. See Hirst's "Obstetrics" (1909), pages 57 and 59.

2. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hicks' sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

Subjective signs of pregnancy, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

Objective signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

3. Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the newborn, due to the gonococcus or other pyogenic germ; produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

The treatment is (1) *Prophylactic.*—Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial.*—Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burned.

4. See Williams' "Obstetrics" (1909), pages 818 and 821; or Hirst's "Obstetrics" (1909), pages 585 and 587.

5. (*a*) *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A.—Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B.—Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both." (*b*) *Indications for version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother, and

(7) in any case where speedy delivery is imperative. (c) *Indications for cesarean section* are: Extreme pelvic contraction or deformity in which delivery by forceps or version or symphyseotomy is impossible, and in which craniotomy is either impossible or would be more dangerous to the mother; the presence of extreme atresia of the vagina; rupture of the uterus; sudden maternal death.

6. See Williams' "Obstetrics" (1909), pages 800, 814, and 815; or Hirst's "Obstetrics" (1909), pages 574, 575, and 577.

7. See Williams' "Obstetrics" (1909), page 194; or Hirst's "Obstetrics" (1909), page 210.

8. See Williams' "Obstetrics" (1909), pages 134 and 298; or Hirst's "Obstetrics" (1909), pages 120 and 343.

9. See Williams "Obstetrics (1909), page 199; or Hirst's "Obstetrics" (1909), page 188.

10. See Williams' "Obstetrics" (1909), page 190; or Hirst's "Obstetrics" (1909), page 205.

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 1248; or Da Costa's "Surgery" (1908), page 1181.

2. See Rose and Carless' "Surgery" (1908), page 282; or Da Costa's "Surgery" (1908), page 377.

3. See Rose and Carless' "Surgery" (1908), page 598; or or Da Costa's "Surgery" (1908), page 1202.

4. See Rose and Carless' "Surgery" (1908), page 1255, or Da Costa's "Surgery" (1908), page 1202.

5. See Rose and Carless' "Surgery" (1908), page 475; or Da Costa's "Surgery" (1908), page 400.

6. See Rose and Carless' "Surgery" (1908), pages 622 and 630; or Da Costa's "Surgery" (1908), pages 500 and 601.

7. See Rose and Carless' "Surgery" (1908), page 328; or Da Costa's "Surgery" (1908), page 401.

8. In *neurotomy* the nerve is cut; in *neurectomy* a piece of the nerve is excised.

9. In *dry synovitis* there is little or no fluid present; in *suppurative synovitis* there is a purulent distention of the synovial sac. The latter form requires drainage, while the former does not.

10. See Rose and Carless' "Surgery" (1908), page 654; or Da Costa's "Surgery" (1908), page 548.

HYGIENE.

1. *Hygiene* is the science and art of all that tends to the maintenance and improvement of health, the prevention or shortening of the duration of diseases, and the prolongation of life.

Health is the condition in which all the functions of the body and mind are performed normally.

Disease is the condition in which there is some departure from the normal in the mental or bodily functions.

2. "Relative humidity is greatest near the surface of the earth during night, when the temperature, being at or near the daily minimum, approaches the dew point; it is also great in the morning, when the sun's rays have evaporated the dew, and the vapor is as yet only diffused a little way upward; and it is least during the greatest heat of the day. . . . Humidity of the air is very generally supposed to be associated with the spread or prevalence of disease; much moisture in the air favors the continuance of colds, but at the same time appears to relieve bronchitis by assisting expectoration and the general discharge of mucus." (Notter and Firth's *Hygiene.*)

3. Parkes summarizes *the practical points of ventilation* as follows: "(1) When air is heated it expands and tends to rise; when air is cooled it contracts and tends to fall. (2) Cold air tends to enter a room and to move about very much as water would; and this holds true so long as the temperature of the fresh air remains lower than that in the room. (3) The extent of inlet provision for fresh air is not quite of the same importance as that for the exit of foul air; for if foul air is extracted in sufficient quantities fresh air will enter somehow to replace it. (4) The inlet provision for fresh air should average 24 square inches for each individual; the provision of inlet areas somewhat larger than those of exit tends to minimize draughts. (5) Inlets should be as low in the room as possible, viz., just above the floor (so as not to raise the dust) if the outside air is warm or has been warmed prior to entry, but at a height of about 5 feet if the outside air is cold; otherwise unpleasant draughts are experienced. As a further protection against unpleasant draughts when cold air is admitted, the incoming air should be directed upward; while hot air, since it tends to rise, should be directed downward. (6) Outlets should be as high as possible, and preferably close to or in the ceiling; and they should have their extractive powers maintained by means of heat or an exhaust fan, or they are liable to act as inlets. (7) Where possible outlets should be so placed that the vitiated air is drawn toward them before mixing with the general air of the room. (8) There is a tendency for fresh air to take a direct course to the outlets, and this must be counterbalanced by a judicious selection of the relative positions of inlets and outlets. (9) Methods of ventilation devised to ventilate *crowded* premises are generally inefficient, unless the incoming air can be warmed in winter to about 60° F.; for efficient ventilation by cold air cannot be tolerated, and there is a great tendency among workers to close all ventilating inlets. (10) With less than 250 cubic feet of space per head no ventilation can ever be satisfactory which is not aided by mechanical force. (11) The source of the incoming air should be considered. It should not be borrowed from adjoining rooms, but taken direct from the outside. One great advantage of the more expensive mechanical system of ventilation is the fact that sufficient air can always be obtained from a source which is known and selected. (12) Ventilation dependent on the extraction of foul air is often more convenient than that in which propulsion is mainly relied upon; but the purity of the air is not easily provided for or guaranteed. (13) If warmed air is forced into a room it should only be raised to a temperature sufficient to prevent a feeling of cold (about 60° F.) More highly heated air is often felt to be overdry and unpleasant."

4. The most reliable sources for pure drinking water are spring water and deep well water. The best methods of purification are boiling and filtration (in a clean filter).

5. *Diseases of domestic animals communicable to man:* Glanders, anthrax, tuberculosis, rabies, aphtha, tapeworm and other intestinal parasites, ringworm, echinococcus, diphtheria.

Animals should be inspected before they are slaughtered, and the meat should also be inspected afterwards.

Red meats (beef, mutton, venison) have been prohibited to patients with gout and rheumatism; also sometimes to patients with gastrointestinal or kidney troubles. The reason for this prejudice against red meats was the belief that they acted as an irritant on the kidneys and so interfered with elimination, and caused autointoxication. This has not been substantiated.

6. Exercise increases the force and frequency of the heart's action, and so increases the circulation of the blood all through the body. Its effect on the nervous system is not settled; probably moderate exercise benefits the nervous system. Exercise increases the elimination of nitrogen by the kidneys.

7. Light color and ready absorption of moisture without a feeling of dampness.

8. Measles, mumps, German measles, scarlet fever, smallpox, whooping cough.

9. For *disinfection of rooms* use formaldehyde gas: *clothing*, use solution of phenol (5 per cent.) for an hour, then boil for an hour; *person*, wash in soap and water, and then with cresol or carbolic acid solution; *bedding*, use steam or formalin; *excreta*, etc., should be passed into vessels containing dilute solution of formalin, of greater quantity than the expected excretion; *sputum* should be burned.

10. *Vital statistics* comprises: Past and present facts bearing on population, age and sex distribution, births, marriages, deaths, diseases, health, and expectation of life of each class in the community.

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*.	W. H. Sanders, Montgomery.	Montgomery	
Arizona*.	Ancil Martin, Phoenix.	Phoenix	Oct 2
Arkansas.	F. T. Murphy, Brinkley	Little Rock.	Nov. 14
California*.	Chas. L. Tisdale, 929 Butler Building, San Francisco.	Los Angeles	Dec 5
Colorado.	David A. Strickler, Empire Building, Denver.	Denver	Oct 3
Connecticut*	Chas. A Tuttle, New Haven	New Haven	Nov. 14
Delaware.	J. H Wilson, Dover.	Dover	Dec. 12
Dist. of Col'ba.	Geo. C. Ober, Washington.	Washington.	Oct. 12
Florida*.	I. D Fernandez, Jacksonville	Jacksonville.	Nov. 7
Georgia	T. H. Goss, Athens.	Atlanta	
Idaho*.	O J. Allen, Bellevue.	Wallace.	Oct 3
Illinois.	J. A. Egan, Springfield	Chicago.	
Indiana.	W T. Gott, Crawfordsville.	Indianapolis.	
Iowa	G H. Sumner, Des Moines.	Des Moines.	Sept. 19
Kansas	H. A. Dykes, Lebanon	Topeka.	Oct. 10

Wyoming	A. B. Tonkin, Riverton	Laramie		

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE TREATMENT OF SYPHILIS WITH SALVARSAN. By Dr. WILHELM WECHSELMANN of Berlin, Dr. PAUL EHRLICH of Frankfort-on-Main, and ABR. L. WOLBARST, M.D., of New York. 175 pages; cloth; illustrated; price $5.00. Rebman Company, Publishers, New York.

THE WASSERMANN SERODIAGNOSIS OF SYPHILIS IN ITS APPLICATION TO PSYCHIATRY. By Dr. FELIX PLAUT. 188 pages; paper. The Journal of Nervous and Mental Disease Publishing Company, Publishers, New York.

INTERNATIONAL CLINICS. Vol. I, 21st Series. By HENRY W. CATTELL A.M., M.D. 300 pages; cloth; illustrated; price $2.00. J. B. Lippincott Company, Publishers, Philadelphia.

EINFÜHRUNG IN DIE EXPERIMENTELLE THERAPIE. By Dr. MARTIN JACOBY. 180 pages; paper; illustrated; pamphlet price 5.00 M., bound 5.80 M. Julius Springer, Publisher, Berlin.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. By Dr. L. KATZ. 48 pages; paper; illustrated. Curt Kabitzsch, Publisher, Würzburg.

INANITION BEI ERNÄHRUNGSSTÖRUNGEN DER SÄUGLINGE. By Prof. AD. CZERNY. 24 pages; paper. Carl Marhold, Publisher.

SCIENCE FROM AN EASY CHAIR. By Sir RAY LANKESTER, K.C.B., F.R.S. 423 pages; cloth; illustrated; price $1.75 net. The Macmillan Company, Publishers, New York.

THE PRACTICAL MEDICINE SERIES. Vol. I. GENERAL MEDICINE. By FRANK BILLINGS, M.S., M.D., and J. H. SALISBURY, A.M., M.D. 405 pages; cloth; price $1.50. The Year Book Publishers, Publishers, Chicago.

ENLARGEMENT OF THE PROSTATE. By C. MANSELL MOULLIN, M.D. (Oxon.), F.R.C.S. 176 pages; cloth; illustrated; price $1.75 net. P. Blakiston's Son & Co., Publishers, Philadelphia.

THE EXPERIMENTAL CHEMOTHERAPY OF SPIRILLOSES. By PAUL EHRLICH and S. HATA. 181 pages; cloth; illustrated; price $4.00. Rebman Company, Publishers, New York.

DIE PRAKTISCHE BEDEUTUNG DES SALVARSAN FÜR DIE SYPHILISTHERAPIE. By Dr. S. JESSNER. 73 pages; paper; price 1.80 M. Curt Kabitzsch, Publisher, Würzburg.

NEW AND NONOFFICIAL REMEDIES. THE AMERICAN MEDICAL ASSOCIATION, Publishers, Chicago. 282 pages; cloth; price 50 cents; paper 25 cents.

HOSPITAL MANAGEMENT. By CHARLOTTE A. AIKENS. 488 pages; cloth; illustrated; price $3.00 net. W. B. Saunders Company, Publishers, Philadelphia.

THE CARE OF THE BABY. By J. P. CROZER GRIFFITH, M.D. 12mo, 455 pages, cloth, illustrated, price $1.50 net. W. B. Saunders Co., Publishers, Philadelphia.

THE FATS. By J. B. LEATHES, M.A., M.B., F.R.C.S. 133 pages; cloth; price $1.25 net. Longmans, Green & Co., Publishers, New York.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended August 19, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	522	
Diphtheria	162	
Measles	166	
Scarlet Fever	49	
Smallpox	—	
Varicella	9	
Typhoid Fever	183	
Whooping Cough	43	
Cerebrospinal Meningitis	6	
Malarial Fever	—	
Totals	1,140	

Non-Operative Treatment of Cancer of the Uterus.—Luigi Mangiagalli has made a careful examination of all the measures used in the treatment of cancer of the uterus, including ablation of the tumor, curettage, thermocauterization, etc. He finds that all drugs are useless; opotherapy has had no results; trypsin has not cured; cancerous serotherapy has proved valueless; erysipelas toxins are too dangerous for general use; bacteriotherapy of several kinds has failed; fulguration applied to inoperable cases after a partial operation has shown undoubted benefits, lessening of pain, sepsis, hemorrhages, and long absence of recurrences. But in spite of this it has been seen that ablation, carefully and thoroughly done, has had better results than any of these methods, and up to date must be the preferred treatment of all early cases.—*L'Obstétrique.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended August 18, 1911:

CHOLERA

Places	Date	Cases	Deaths
Austria-Hungary: Cattaro	July 6–22	3	..
Trieste	Aug. 8–14	9	3
India: Calcutta	June 18–24	..	37

THE PITUITARY BODY.*

BY CHARLES W. HITCHCOCK, M.D.

DETROIT, MICH.

CONCERNING the pituitary gland, or hypophysis cerebri, much study and more speculation have been indulged in, but accurate knowledge has only of late given promise of possible development. The last word has by no means as yet been said concerning this obscure corner of anatomy, physiology, and pathology, and the very obscurity in which it has so long been enshrouded may serve as our apology for treating the subject in a manner open to the accusation of being perhaps somewhat elementary.

"The pituitary body is a small reddish-gray mass," says Kirke,[1] "occupying the sella turcica of the sphenoid bone." According to Zander, quoted by Dock,[2] its size is somewhat variable, 6 to 10.5 mm. in sagittal, 10 to 14.5 mm. in vertical, and 5 to 9.75 mm. in transverse diameter, and weighing on the average in health 0.6 grain.

Facts of development account for the two parts of which it is largely made up and for the fact that these have separate blood-supplies. Its anterior (non-nervous) lobe is derived from Rathke's pouch of the pharyngeal ectoderm, while its posterior lobe (the nervous portion) is developed from the midbrain ectoderm, these processes growing up and down respectively, the connection of the former with the oral cavity disappearing entirely at the level of the sphenoid while the connection of the latter becomes much narrowed but persisting as the infundibulum.

The anterior portion is much the larger and its structure bears a resemblance to that of the thyroid body. If a more detailed account of the histological structure of the hypophysis be sought, it may be said that the anterior portion is made up of follicles of various shapes, containing large chromophile cells, with acidophile and basophile granules, and smaller paler cells of indistinct outline, called "chief cells" by one observer (Stieda quoted by Dock); while according to Benda, the various cells represent stages of a single class, the chromophile cells being more numerous in middle life, the chief cells in old age. The posterior lobe is made up of connective tissue, blood-vessels, pigmented cells of various sizes and shapes, and also cells like those in the anterior lobe. The "pars intermedia," partly glandular, with colloid in tubules and vesicles, and partly vascular, is of necessity extremely thin, so closely adjacent are the anterior and posterior lobes.

The relations of the pituitary body with the thyroid have long been suspected and of late years the relations of the hypophysis with the ductless glands in general, particularly the adrenal system, have been the subject of no little speculation as well as more scientific investigation.

The physiology of this small portion of the organism has proven a complex affair and is still in a somewhat unsettled state, Tigerstedt[3] stating that "from results thus far before us no positive conclusion can be drawn as to the normal workings of the hypophysis," and Dock reaches no more satisfactory conclusion, in view of Schaefer's experiments, than that "it is probable the relation of the pituitary body to other organs and to diseases, concerning which so many brilliant speculations have been made, is closely associated with the production, by various parts of the pituitary, of 'hormones,' activating or stimulating substances with obscure but important effects on numerous organs, ductless, sexual, and others, as well as upon metabolism in its broadest meaning, including growth." Results of other work in this direction we shall later see.

This obscure organ, once termed by Van Gehuchten "l'organe, enigmatique," bids fair, however, to have more light thrown upon it through the patient efforts of a host of later energetic workers. They may, perhaps, receive some animating impulse from the fascination which attaches just now to the complex problem of the ductless glands in general.

The rather commonly accepted conclusion that the pituitary body is essential to the maintenance of life had some doubt cast upon it by statements of Horsley who experimented upon dogs. It is believed, however, that his results were due to incomplete hypophysectomies, for Reford and Cushing,[4] raising this very question concerning the hypophysis and seeking to confirm or refute Horsley's findings, conclude that their careful experiments on dogs only further sustain Paulesco's earlier contention that a total hypophysectomy is incompatible with the continuance of life, although its continuance in their cases was longer than that observed by Paulesco. Such a conclusion as to the importance of the pituitary body would seem to place obvious limitations upon the surgery of this region, restricting it to removal of tumors or, in other cases, to partial hypophysectomies.

In another communication as to "The Functions of the Pituitary Body," Cushing[5] describes studies on this organ which he made (1) by simulated oversecretion by injections, feedings, etc.; (2) by simulated undersecretion through partial or total removal or destruction of the gland; (3) by observing alterations of the gland in disease and in various states of functional activity, and (4) by noting hypophyseal changes secondary to lesions of other ductless glands. He refers also to the earlier observations of Marie, Howell, Oliver, Schaefer, et al, which established that the glandular extract even after being raised to the boiling point led to a rise in

*Read before the District Society of Neurology and Psychiatry, April 6, 1911.

blood-pressure and that this substance was confined to the pars nervosa and its epithelial investment. The reaction following its injection was found to be more enduring than that produced by adrenalin and to be accompanied by a definite slowing of the pulse. And it was later discovered that this principle distends the kidneys and increases the flow of urine. Like adrenalin, it dilates the pupil.

In view of the commonly accepted belief that the occurrence of acromegaly establishes conclusively disease of the pituitary body, it is most interesting to note Cushing's statement that "the actual association of an hypophyseal lesion with acromegaly is by no means generally conceded, despite the obvious tumor or enlargement so frequently observed, for a number of autopsies of undoubted cases of acromegaly have shown a pituitary body which has been regarded as practically normal."

As a result of his investigations Cushing concluded (*a*) that the pituitary body is a double organ, the secretion of its "anterior and solidly epithelial portions" discharging into the blood sinuses in that part of the gland, and the hyaline substance, apparently the secretion from the epithelial investment of the posterior lobe, entering the cerebrospinal space by way of channels in the posterior part; (*b*) that the secretion of the posterior part does not seem to be so vitally essential to physiological equilibrium as that of the anterior lobe; (*c*) that alterations of the gland, which in their earlier stages may represent an hypertrophy and in their later progress assume the characteristics of an adenoma, are common in acromegaly and gigantism, and that these conditions represent the consequences of hyperactivity of the pars anterior; (*d*) that total removal of the pars anterior leads to death with a peculiar train of symptoms, while its partial ablation leads to obvious disturbance of metabolism, oftentimes accompanied by adiposity, and in the young by a persistence of infantilism, or, in adults by a loss of secondary sexual characteristics already acquired. Cushing further concludes in view of the apparent interrelation of many of the glands of internal secretion that it is quite probable that certain of the symptoms accompanying hypophyseal disease may be due to secondary changes in other glands, which follow upon the primary lesion of the hypophysis. Such a conjecture certainly complicates rather than simplifies the problems of the hypophysis. The possible complexities of its investigation are further hinted at by the fact noted by Cushing (in his oration June, 1909) that "it is impossible to remove, probably partially to remove, the hypophysis without producing marked alterations in all the other glands, thyroid, parathyroid, adrenal, testicle, ovaries, islands of Langerhans and thymus."

Although it is believed that deviation from the usual functioning of the normal hypophysis is quite as frequent as such departures from the normal in the case of the thyroid, the clinical manifestations of such irregularities have been but poorly understood. It is believed, however, that hyperpituitarism, due to an increased activity of the pars anterior, and hypopituitarism, due to a diminished activity of the same epithelial structure, ought now to be differentiated; the former indicated by condition of overgrowth, gigantism, when commencing in youth, and by acromegaly, when developing at a later period, the latter expressed chiefly by an excessive deposition of fat with persistence of infantile sexual characteristics when the process starts early, and a loss of adolescent features if appearing in adult life. Further, it is highly improbable that all of the functional abnormalities of the hypophysis are due either to a tumor of the gland itself or to pressure of a growth in its immediate vicinity.

The recent investigations of Wiggers[8] concerning the physiology of the pituitary lead him to conclude that while the anterior lobe develops a secretion essential to life and to normal metabolism and development, this substance has thus far resisted extraction by various solvents, and for this reason its chemistry and physiological properties are still unknown; while, on the other hand, the posterior lobe, not of vital importance, secretes a substance extractable bl water, glycerin, or salt solution, resisting boiling, but not demonstrated to be identical with the secretion of the anterior lobe or as representing its vital principle. He finds that while these extracts constrict peripheral vessels, thus raising blood-pressure, this constriction is not equally pronounced, for the renal vessels are dilated during its action; and he states that while these extracts are generally stated to slow and strengthen the heart, careful tracings show a depressing influence to be the most constant and characteristic one. The slowing and depression are largely attributable to a direct cardiac action. Only in its blood-pressure-raising action does pituitary extract resemble adrenalin. In addition to its cardiovascular effects, this extract increases the excretion of urine and inhibits the flow of pancreatic juice, but to just what substances these effects are due is not as yet known.

As to the interrelation of the hypophysis and other glands of internal secretion, excepting the thyroid, Parhon and Golstein[7] cite first the amenorrhea present in the cases of gigantic or acromegalic women, as also the impotence, accompanied often with a glabrous state of skin of face and body, in the case of men similarly afflicted, and they have also noted facts which argue for the possibility of the appearance of early puberty under the influence of a lesion of the pituitary body, although they do not lost sight of the opposite nature of early puberty and infantilism. While these relations do not seem to be defined as yet with entire exactness, still they regard it as established that there are close relations between the pituitary and the sexual organs.

Similarly, the relations of the hypophysis and the pancreas are strongly suggested by the frequent occurrence of diabetes and glycosuria in patients the subjects of acromegaly.

Though the persistence of the thymus in certain acromegalics raises the question of some relation between this gland and the hypophysis, this abnormal persistence may possibly be explained by the insufficiency of the sexual glands, so frequently met with in acromegaly and gigantism, for several facts tend to demonstrate the existence of an antagonism between the functions of the thymus and those of the sexual glands.

The liver is frequently enlarged in acromegaly. On the other hand, the urea is very often diminished, and more rarely, as in complicated cases of diabetes, glycosuric or other, it is increased. The kidneys, too, may be increased in volume, and albuminuria and polyuria are symptoms frequently met with. Hypertrophy of the spleen and of the lymphatic glands in acromegaly suggests the existence of a relation between these organs and the hypophysis. It is to be noted that these French authors assume apparently as proven the hypophyseal etiology of

acromegaly. They admit the as yet indefinite character of the suggested relations between the hypophysis and the other glands of internal secretion, simply claiming it as more than probable, but regarding as among future problems the determination of how far and in what manner each one of these glands influences the nervous system or is influenced by it, and to what extent the nervous system may intervene in the pathogeny of acromegaly. They also report a case of tumor of the hypophysis without acromegaly, and cite further the experiments of Cerletti as indicative of the errors into which we are likely to fall in jumping too readily to large conclusions from small premises. There is much room for possible error, since Cerletti, having experimented for some time and on a number of animals in giving injections of hypophyseal extract, observed as a seeming result a general retardation in bodily development, more especially of the skeleton, yet it seems to be fairly well established that hyperpituitarism leads to quite another result.

Quite similar, as to present uncertainty concerning interrelation of the glands of internal secretion, are the conclusions of Hoskins,[8] who considers these glands *scriatim*. The effect, he says, of experimental hyperpituitarism upon the thyroid has been so little studied that the evidence is on the whole quite inconclusive. The effect upon the thyroid of hypopituitism has been studied in cases of extirpation of the thyroid for relief of acromegaly, and also in hypophysectomies in young dogs, hypertrophy of the thyroid quite uniformly resulting. "Taken altogether," he says, "the evidence supports a theory that the two glands are synergic, and either can, to some extent, in case of need, function vicariously for the other."

A possible relation of the pituitary to the sexual organs is hinted at by the cessation of menstruation in the female and impotence in the male, which are recognized initial symptoms of acromegaly. Observations as to hyperpituitarism afford as yet but negative results, and though the inference is drawn, from the genital atrophy ensuing after partial ablation of the anterior lobe, that the pituitary normally stimulates the sex glands to activity, it is freely admitted that further evidence is necessary before a final conclusion is reached.

Nor is there any valid ground as yet upon which to base any conclusions as to the relationship of the pituitary and adrenals, while the possible connection between the pancreas and pituitary is veiled in just as great doubt, which also enshrouds any possible pituitary-parathyroid relationship. This delightful uncertainty seems so far to crown all efforts to definitely confirm suggested relations of the pituitary with the glands of internal secretion.

As to the functionating of the hypophysis, Delille[9] says: "In an hypophysis in full functioning will be found numerous chromophile cells, an abundant colloid substance, both intracellular and extracellular; in a gland exhausted or nearly so will be seen slightly granular cells, not large, homogeneous, poorly stained, some pale and scattered nuclei, some chromophilic cells without vacuoles or granules."

Delille refers to the fact that the histological examinations seem to prove that the anterior lobe is the active part of the hypophysis though he then quotes various explanations to reconcile this apparently paradoxical finding. He says the (French) physiologists have established in an "undeniable manner" that the extracts of the posterior lobe alone possess a cardiovascular action, though the histological finding would quite agree with the recent conclusions of Cushing. He remarks incidentally that the suprarenal still offers identical difficulties of study, being formed from two embryologically different points of origin.

As to the toxicity of the hypophyseal substance, large doses are more or less toxic and may lead to the death of the animal, but in ordinary physiological and therapeutic doses but small risks are run.

One of the French investigators, M. de Cyon, believes that the hypophysis produces several active substances. One, hypophysin, acts particularly on the force and number of beats of the heart, while another acts particularly upon the vasoconstrictors. Hypophysin, which is probably an organic combination of phosphorus, considerably increases the strength of the pulse and produces a notable slowing rarely preceded by a short acceleration. This slowing is accompanied by an increase of blood-pressure. The pulse produced by extracts of the hypophysis, especially by those which have been prepared at the boiling-point, has the character of reënforced contractions, lasting 5 to 15 minutes and tending to manifest themselves in series lasting 60 to 100 seconds and more, this series being neither prevented nor interrupted by stimulation or section of the pneumogastric.

In reviewing the trophic effects produced by the hypophyseal extracts, Delille observes that they stimulate metabolism, modifying the excretion of nitrogen, phosphorus, and calcium. The effects upon development and growth are as yet too little known to warrant positive conclusions. None of the animals, however, fed with these extracts exhibited any acromegalic changes.

Effects upon other organs following intraperitoneal injections of an extract of the whole gland have been carefully noted. Small doses keep the hypophysis in hyperfunctioning during a long time (6, 10, and even 14 months); medium and strong doses of the extract, on the other hand, more or less quickly exhausting it, proportionally to the amount administered. Under the influence of the extract of the whole gland the suprarenal hypertrophies and may double in size but histological examination reveals a hypofunctioning. While this treatment at first seems to stimulate the suprarenal secretion it leads soon to exhaustion, and hence the state just referred to of macroscopic enlargement and a lowering of function.

The thyroid is the seat of various cellular changes; there is a diminution in colloid substance and a probable hypothyroidism, probably due to vasoconstricting effect produced upon the thyroid by the hypophyseal injections. Neither testicles nor ovaries present appreciable change. The liver shows some congestion and a granulo-fatty degeneration in its periphery. Examination of the spleen is negative; the kidney frequently shows a mild congestion, and the glomeruli are almost always increased in volume. The lungs, too, are mildly congested, while the cardiovascular apparatus presents no significant alterations.

Changes in the hypophysis in various diseases have been noted, but the observations have been too few or the changes too insignificant or too inconstant to make them worthy of note.

Pal[10] concludes, from experiments as to the effect of the extract upon the arteries, that upon the carotid, mesenteric, and femoral arteries of cattle, the same effect is produced as follows the similar

use of adrenalin, but that the action upon the vessels of the heart and kidneys is diametrically opposed to that of adrenalin, as determined by numerous experiments.

Crowe and Cushing[11] in their experiments on the transplanting of the hypophysis confirmed Halsted's principle that, essential to the success of such experiments, a preliminary physiological deficit is necessary. They transplanted hypophyseal tissue into the rectus muscle, the marrow of the tibia, and into the cerebral cortex, killing their dogs in 16, 17, and 18 days, respectively. Cachexia hypophyseopriva, evidenced by arching of the back, subnormal temperature, and general dulness, had developed in all prior to death.

Cushing and Goetsch[12] confirm the suggestion made by Herring (1908) that the granular hyaline or colloid masses in the posterior lobe of the hypophysis represent products of secretory activity of the epithelial investment, which find their way through the tissue interstices of the pars nervosa and ultimately discharge between the ependymal cells into the cavity of the third ventricle. This suspicion was regarded as confirmed by finding in the cerebrospinal fluid a substance giving the same reactions as those produced by the extract of the posterior lobe itself.

Houghton and Merrill[13] after elaborate experiments confirmed a diuretic action following the intravenous injection of the active principle of the gland, but concluded that this was due rather to an increased blood-pressure than to a specific hormone. Wiggers[14] has investigated the influence of the pituitary extract as a pressure-raising drug, and finds it to possess advantages over adrenalin in that it causes a prolonged rise of pressure after a single intravenous injection, which makes it especially valuable to maintain a proper supply to the brain during hemorrhage. Further physiological research will undoubtedly bring us still more exact knowledge of the effect on life produced by this small structure.

As to its pathology, we shall find that the conclusions of Münzer[15] are quite in agreement with those reached by other investigators. He concludes that the pathologic changes of the hypophysis may be either atrophic, hypertrophic, or those incident to tumor; that mechanical disturbances and purely functional alterations must be differentiated, the former being especially likely to cause anomalies of vision; that acromegaly probably should not be regarded as dependent upon primary hypophyseal changes; that quite commonly tumor of the hypophysis is associated with "dystrophia adiposogenitalis," though this is of unknown cause. He notes, too, that coincidentally with disease of the hypophysis other glands are affected and myxoedema or diabetes may be present. He believes the hypophyseal tumors as operable and that the vascular glands form a combined system. Acromegaly he regards as a polyglandular affection.

Hecht[16] recites that particularly our knowledge of the neoplasms of the hypophysis has been enriched within the past few years by laboratory research, and neuro-surgical work as well as by expert radiography, and reports a case of tumor of mixed type, reviewing the histology, pathology and symptomatology. "Hypophyseal tumors," he says, "are on the whole slow growing and benign. In size they may vary from a millet-seed up to a pea, and occasionally attain to the size of a walnut, but sarcomata, having the dimension of a hen's egg or a male fist have been reported." They may excavate the sella turcica, penetrate through the base, and grow even into the nasal sinuses, and a case has been reported of extension into the orbit. Boyce and Beadles (in a paper referred to by Hecht) divided these tumors into: (1) Abscesses and granulomata; (2) hematomata; (3) tumors of the infundibulum and posterior lobe; (4) tumors of the membranes surrounding the hypophysis, as lipomata; (5) glandular neoplasmata; (6) teratomata; but of the 77 cases collated by them 56 were of glandular origin and 3 were teratomata.

Though there have been zealous contenders for the constant relation of hypophyseal enlargement to acromegaly, the absence of this disease condition in cases of undoubted tumor and enlargement has been eloquently pointed out as conclusively refuting the contention. Hecht concludes that "it is now quite well settled that a tumor may be present without causing acromegaly, and conversely acromegaly may exist without a tumor being found present."

The symptoms of tumor of the hypophysis may be so little localizing as in Hecht's case, which presented vomiting, headache, disturbed vision with choked discs, and paralysis of right external rectus, as to point merely to the presence of an intracranial growth, though alterations of the visual field, changes in the fundus, unilateral or bilateral blindness are among the symptoms most constantly met. Many cases, therefore, find their way into ophthalmological literature.

Ocular palsies are not unknown, nor are various pupillary alterations, even total iridoplegia. Headache, too, is a not infrequent symptom, and may be associated with pain in the orbit. The fifth nerve seems to be sometimes involved, and the pain may be most intractable. The headache may be diffuse, frontal or temporal, or involving both frontal and temporal regions. Increased tension doubtless accounts for much of the pain present. At least two investigators agree that sundry modifications of speech are rather characteristic of tumors of this region.

Lewis[17] speaks of acromegaly in connection with hypophyseal tumors as if he regarded the relation as much more constant than that found by other writers. The most common lesion in cases of acromegaly he regards as adenoma of the anterior lobe. Tumors arising from the pars intermedia he finds to be rare, having encountered but three cases, of which two gave rise to no symptoms.

Halstead [18] reported to the Chicago Neurological Society two cases operated on by him, one, a man of 39, presented six months after operation; the other, a woman, who died the day following operation. His first patient dated back two years the commencement of his trouble, the initial symptoms being a frontal headache of a pricking character. A year later his eyesight began to fail, and later his visual fields were narrowed, but diagnosis was not made until the occurrence of bitemporal hemianopia and bilateral optic atrophy.

Halstead's method of operation was as follows: Following a high tracheotomy and the insertion of a Trendelenburg cannula, the upper lip was raised and its mucous membrane incised, the soft tissues freed, and the nose drawn up with retractors, the septum being loosened with bone forceps. The turbinates, vomer, and perpendicular plate of the ethmoid were then removed, and approach was then had through the sphenoidal sinus, a blue-colored pulsating mass coming into view which was easily removed by the

curette. The cavity was packed, the septum sutured back in place, and the mucous membrane of the mouth replaced and sutured. A high temperature prior to removal of the packing was the only noteworthy occurrence in an uneventful recovery. His headache entirely disappeared and the vision of the right eye improved from 4-200 to 6-15 and the left from 5-200 to 6-22. The growth Halstead regarded as an epithelial tumor. This route for operation is, at least, commendable in this respect, that it leaves no scar.

Another route worked out by Kanavel[19] and called the infranasal is similarly commendable. This plan consisted in the deflection of the cartilaginous septum and the removal of a section of the vomer and the anterior wall of the sphenoid. Kanavel's patient so operated on lived five weeks after the operation. A preliminary diagnosis of sarcoma was made, the growth being of the size of a walnut. Less free from cosmetic defect is the route from the side, a temporo-sphenoidal avenue of approach, advocated by some.

No attempt has been made by the writer to collect the various hypophyseal tumors operated on and recorded in the literature. The foregoing cases are merely referred to as illustrative of the surgical treatment of these tumors which, according to Aldren Turner and Grainger Stewart,[20] fall in their general aspects into two types, the first of which is characterized by bilateral, temporal hemianopsia, with pallor of the inner half of the optic discs, without optic neuritis; by an absence of general symptoms, but accompanied with some mental impairment, such as loss of memory and sluggish mental action. Motor, sensory, and reflex symptoms are absent. In the second type, the general symptoms of intracranial growth are well marked—frontal headache, optic neuritis, and mental impairment being early in evidence. In this type acromegaly never develops and loss of vision is rapid.

Bitemporal hemianopsia may appear early, but quickly gives place to blindness, earlier on one side, hemianopsia being sometimes observed on one side and blindness on the other. The complete blindness which ensues is entirely disproportionate to any fundus changes which are to be found. Inattention, loss of memory, childish conduct, and increasing dementia characterize these cases.

Impairment of function of the third and sixth nerves on one or both sides is not seldom in evidence. Generalized epileptic attacks, muscular hypertonicity, slight spasticity of the limbs are sometimes seen. The deep reflexes are exaggerated and the superficial diminished. If there be lack of control of sphincters it is attributable to the mental failure.

A research investigator of pituitary problems from the chemical side (whose work is still unpublished) advises the writer that its chemistry is rather unsatisfactorily worked out and that comparatively little is now positively known. Cholin is found in the anterior portion, apparently associated with lecithin; its existence in the posterior portion is as yet a matter of doubt. To the presence of the cholin is probably due the fall in blood-pressure occasionally observed after the injection of the extract. Whether or not the blood-pressure raising agent contained in the pituitary extract is of proteid nature is one of the problems yet to be solved by the physiological chemist.

Nor is this by any means the only unsolved question connected with this organ, for degeneration of the pituitary is followed by premature senility, and this is in itself suggestive of possible farther light yet to be shed upon the relation of the hypophysis to the onset of old age; the fact of the blood-pressure raising agent contained in its extract hints at possible relations of the pituitary to arterio-sclerotic changes, and the questions are many and complex which are suggested by the interrelations of the ductless glands, a field of investigation already attracting many and earnest workers. Though Torri noticed a hyperplasia of the chromophile cells of the pituitary body and disappearance of the colloid from the follicles in the majority of cases of pneumonia, typhoid fever, tuberculosis, diphtheria, and other infectious diseases, less definite have been the conclusions of other investigators, and there is need of still further research before the relations of the ductless glands to these diseases and to the problems of life in general are fully understood, though better and better is their importance becoming appreciated, and among them the pituitary seems to play no inconspicuous part.

What, then, is the present status of the hypophysis? It may fairly be said that:

1. Its anatomy, gross and fine, has been thoroughly studied and is well understood.

2. Its physiology is less obscure than formerly, but will doubtless be still more clarified as the result of patient research work. The importance of the pars anterior and the fact that it is essential to life are better emphasized and clearly established. The great resistance of the pars anterior to ordinary extractives has made difficult its more thorough investigation.

3. While there seems a basis for the suspected relationship of the glands of internal secretion, this relationship is not as yet clearly defined, and perhaps the least definitely understood is the part played by the pituitary body.

4. Its physiological chemistry is still under investigation, presenting as yet but few facts definitely known and clearly settled.

The literature of the hypophysis has already attained truly dignified proportions, in spite of the seemingly little positive knowledge which we possess, and of this the writer has been able to invade but a small portion. He presumes to hope, however, that this meager review of the present status of the hypophysis may serve to make clearer the complexity of its problems and possibly awaken a deeper interest in its further study.

STUTTERING, ITS ORIGIN AND TREATMENT.

By N. J. POOCK VAN BAGGEN.

THE HAGUE, HOLLAND.

During my visit to America I frequently had the opportunity to state the difference between the treatment of stutterers in America and that employed in Holland. For a long time it has been my intention to publish the present article, in which I shall endeavor to give a short review of the etiology and the pathology as they are known here and of the therapeutics which I have applied during seven years with the most satisfactory results. There is perhaps no disease which has been more subject to the most contradictory modes of treatment than stuttering.* The multiplicity of ways of treating the stutterer were chiefly the result of the want of knowledge of the origin of the disease. When we review the works of the different authors who have written about stuttering we see that stuttering and its origin have been studied most carefully, and with the sincerest effort to uncover the hidden source of this evil. One can readily understand how those earnest investigations could lead to the most opposite conclusions. Later on there comes greater similarity in the result. Instead of contradicting each other the facts corroborate each other and readily come to a clear understanding of the main cause of the disease. However, even with this knowledge of the origin, stuttering remains one of the speech defects which is most difficult to cure, and which requires from the specialist as well as from the stutterer himself the utmost endeavor, patience and energy. Absolute confidence in the physician and the strictest obedience are required from the patient. But too often the cure is halted, and even fails altogether, by the carelessness and neglect of the patient. The false ideas about stuttering and its origin still prevalent among the laity also prove to be a great hindrance to the cure.

*As the words stuttering and stammering are often confused by English authors the following explains the difference between them: The stutterer pronounces all consonants and combinations of consonants correctly; he can speak normally when his speech is not interrupted by incoordinate movements of the breathing, vocal, or articulating muscles. The stammerer cannot pronounce certain consonants and combinations of consonants, while the continuity of his speech is not broken.

Many are they who believe that stuttering is simply a bad habit, a negligence in speech. I have met with several parents who punished their children severely for stuttering, and often it is not a slight task to make them understand that their doings aggravate the evil considerably and sometimes even render it incurable. It occurs, also, frequently that the patient is given the advice not to take any notice of his impediment, for with time it will pass away by itself. Worse advice could hardly be given, because by delaying the cure not only will the disease itself have time to take deeper root, but also the derangements in the whole nervous system which show themselves only too soon with the stutterer will have full opportunity to develop and so complicate the case. Therefore, quick interference is needed. The younger the patient and the more recent the disease the greater is the prospect of cure. Only with the form of stuttering which often appears in children between two and five years of age the treatment by the specialist is unnecessary, this stuttering being generally due to the rudimentary speech of the child. Training of the articulating muscles is generally sufficient to overcome this difficulty.

To cure a disease it is necessary to look for the root of the evil. Our first concern is the question of etiology. With stuttering this is often difficult because of the variety in the symptoms which accompany the disease. There are, however, certain symptoms or principles by means of which we can invariably state the nature of the affliction. It is important not to be confused by the nervous symptoms which mostly accompany this speech impediment, and which sometimes assume such proportions as to entirely hide the impediment itself.

Observing the stutterer while he is speaking, one will note that the harmonious continuity of speech is interrupted by incoordinate movements, or what is the same, spasmodic contractions of the articulating, vocal, or breathing muscles. Spasmodic contraction of the muscles is caused by abnormal action of the motor nerve fibers. Where there exists a condition of irritability of a motor nerve fiber the voluntary contraction of the muscles is interrupted by movements independent of the will. Those involuntary movements are known as spasms, and thus one can conclude that the origin of stuttering is a spasm due to a morbid condition of irritability of the motor nerve fibers of speech. The motor nerve fibers in action when speech is produced are motor fibers of the nervous trigeminus, the nervus facialis, the nervus hypoglossus, the nervus vagus and of the nerves connected with the respiratory muscles. It is one or more of those nerves which are affected in stuttering. Mostly the nervus hypoglossus and the nervus facialis are affected. According to the nerve which is affected the cramp will affect the articulating, the vocal, or the breathing muscles. When the articulating muscles suffer from the spasmodic contraction the patient is hindered in pronouncing the consonants. Sometimes the lips cannot be used freely; or the cramp is felt at the point or at the back of the tongue. In the first case, the patient will tell you that he has great difficulty in pronouncing *p, b, m, f, v,* or *w;* while in the second case, *l, t, d, n,* or *r;* and in the last case the *k, g, j, s,* or *z* is the cause of the embarrassment.

The spasm appears generally more frequently when forming the breath consonants than when pronouncing the voiced consonants. Also stop con-

sonants prove to be more dangerous to the patient than the continuents. The spasm of the vocal muscles, whereby the pronunciation of the vowels and of the *h* is impeded, occurs less frequently. Of course, the regular breathing is disturbed when there is spasm of the articulating or of the vocal muscles, but this irregularity in breathing is not caused by cramp of the thoracic muscles. It is rarely that we meet with cases where the motive power of speech, the breath itself, is stemmed by a spasmodic contraction of the muscles of the thorax.

Usually the patient has the greatest difficulty in beginning to speak; the initial letter of the initial word of the phrase is most subject to the cramp. When once this obstacle is surmounted the patient speaks fluently and pronounces all the consonants and vowels, even those which he imagines that he cannot form, correctly, and without embarrassment. Momentarily the patient is free from cramp until unexpectedly it reappears and causes him to stutter again.

The spasms are of a clonic or of a tonic nature. The clonic spasm is characterized by a rapid succession of involuntary movements of the muscles. When the stutterer who suffers from it makes an effort to speak the consonant or vowel is uttered over and over again before it is joined to the following vowel or consonant. The tonic spasm shows but one contraction of the muscles which, however, lasts some moments. We see the articulating parts of the mouth of the stutterer affected by this kind of cramp, almost locked together, and the patient is not able to produce a sound before the muscles are relaxed.

The adherent symptoms which accompany stuttering consist in convulsive movements of the face, the head, the limbs or of the whole body. We see the stutterer, in his effort to speak, rolling his eyes, contorting his features. Some jump up and down, while others pound or slap themselves. Sometimes these movements, as already said, take such proportions as to hide entirely the speech impediment. I know of one case where the stutterer was considered a madman, and treated like it. When this patient made an effort to answer a question addressed to him he rolled his eyes and with clinched fists he approached his interlocutor with the most threatening movements of arms and legs; his foam-covered lips were locked tightly together, and large beads of perspiration moistened his brow. When at last the convulsion relaxed the utterly exhausted patient spoke a few words in a scarcely audible voice, but fluently; however, when he tried to continue to speak the same convulsions overtook him. The doctor of the asylum where he was brought for his apparent insanity discovered the real cause of his trouble. The treatment of his speech impediment brought on the desired result.

It has often been stated that the stutterer executes these movements to aid him in his efforts to speak, thus that they are voluntary movements. Later investigations bring forth a contrary view of the cause of those adherent symptoms and we now consider them as involuntary spasmodic movements of which the cause is closely allied to the origin of stuttering; in other words, to the morbid condition of irritability of the motor nerve fibers of speech. The motor nerve fibers of speech are all in close connection with other motor nerve fibers. When the moving impulses, born in the motor center of speech, are obstructed at the afflicted part of the fiber, these impulses strive for an outlet and pass over to other fibers, causing spasmodic contractions or involuntary movements of the muscles associated with the fibers.

Considering the general constitutional disposition and health of the stutterers we find that most of them are highly sensitive and of feeble nervous condition. An excitable and vivacious temperament is a fertile soil for the evil. I cannot agree with those who state that stuttering generally is associated with a scrofulous constitution. Save his peculiar nervous temperament the average stutterer, so far as I have observed, does not suffer from an impaired constitution. Many believe that stuttering is an hereditary evil. This statement is true only to a certain degree. It is not the stuttering itself that is hereditary, but rather the particular condition of the temperament which predisposes the patient to the evil. In unfavorable circumstances this predisposition will develop in stuttering. As unfavorable circumstances may be considered: poverty, worry, care, want of discipline, and spoiling of children, and last, but not least, the intercourse with stutterers. The contact with stutterers and imitating them is only too dangerous for the predisposed temperament.

After what has been said about the origin of stuttering it is evident that the first thing to do when treating a stutterer is to give him a rest. So the stutterer is forbidden to speak. Some do not stutter when they speak in a whisper. These are allowed to whisper, but not more than is strictly necessary. At the same time exercises are given for the breathing, vocal, and articulating muscles. These exercises not only aim at the development of the muscles but also tend to favorably influence the nerve fibers associated to the muscle. Therefore the exercises must be carefully chosen in such a manner as to produce a quiet, regular movement of the muscles by means of which all stuttering is excluded. After some days the patient is allowed to speak, in the beginning only in the presence of the teacher and only for a few moments. At a later period when the patient does not stutter the discourses are prolonged. These early conversations, during which stuttering must be carefully avoided, are for the specialist one of the most difficult parts of the cure. They require the exercise of the greatest tact in leading the conversation in such a manner as to prevent the patient from stuttering. When the latter has spoken fluently for some days with his teacher without any stuttering he is allowed to converse a few moments with his family and friends. When we have succeeded so far we generally notice a rapid progress. The patient regains his self-confidence and the constant apprehension associated with his speech disappears; this has a favorable influence on the entire nervous system. When the cure is completed the patient must remain under the control of the specialist for some time, while also continuing the exercises with increasingly longer intervals. If there are adherent symptoms the exercises for the breathing, vocal, and articulating muscles must be combined with slow, regular movements of the limbs. Those voluntary movements suppress the involuntary convulsions.

When treating a stutterer it is necessary to take into consideration not only the manifest symptoms of the disease but also the temperament of the patient. The timid patient who suffers deeply from the humiliation entailed by his infirmity must be dealt with in a manner different from that with which one deals with the heedless stutterer who

feels only the irksomeness of his impediment. The spoiled, undisciplined child requires firmer management, while the bashful little stutterer must be approached with kindness. The success of the treatment depends much on a good understanding between the patient and the specialist.

The above is only a general view of the treatment that I have employed since eight years with the best results. I hope to be able to refer again to this subject and to give a more ample explanation of the method of cure and of the exercises.

THE VIRTUES OF SALT SOLUTION;

WITH SOME EXPERIENCES WHEN COMBINED WITH ADRENALIN AS AN INTRAVENOUS INFUSION.

By JEROME M. LYNCH, M.D.,

NEW YORK,

CLINICAL PROFESSOR, NEW YORK POLYCLINIC.

The longer I live, and the more I know about salt solution, the more convinced I am of its unlimited virtues. At the same time I remember some near-fatalities from its improper use, or I should say its improper application in too concentrated a solution.

Abderhalden says: "Inorganic salts are usually present in different foods to an extent entirely sufficient for all our demands. An exception to his general rule is the fact that man and certain animals require an additional supply of sodium chloride. Sodium chloride is the only inorganic substance which it is necessary to add to our diet. This is rather remarkable, because both animal and vegetable foods already contain considerable sodium and chloride. The explanation of this exceptional requirement in the case of common salt we owe to C. v. Bunge. Bunge pointed out in the first place that among animals only the true herbivora, and the carnivora, crave salt. The fact is familiar to hunters. They know that wild herbivora — ruminants and solidungulates — frequent the salt licks. Now, the amount of sodium chloride which these animals obtain by their food is about the same per unit of the animal's weight as that obtained by the carnivora in its diet. It is hardly to be said, therefore, that there is a lack of sodium chloride unless we assume that this salt plays a particular part in the organism of the herbivora, an assumption which, in the light of recent investigation concerning the action of the individual ions, no longer seems so improbable. Bunge has shown, however, that vegetable food differs from animal food by the amount of potash which the former contains. The herbivora obtain three or four times as much potassium salt in the food as the carnivora do. All vegetables, especially potatoes, clover, and meadow hay, contain large amounts of potash. We know of but very few land plants which, like the varieties of Chenopodium and Atriplex, contain more sodium chloride than potassium salt. It is easy to account for the high potash content of plants by the distribution of the elements sodium and potassium on the earth's surface. By the weathering of silicate rocks sodium carbonate is formed, which dissolves readily in rain water and trickles down into the earth. The potassium, on the other hand, remains with the other bases combined with silica and aluminum as an insoluble double salt. The latter remains near the earth's surface, while the sodium is flushed out by springs, brooks, and rivers and carried on to the ocean. This accounts for the fact that potassium salts predominate on the surface of the earth, while the ocean is rich in sodium salts, especially the chloride.

"Now why should an increased amount of potassium salts create a demand for a greater supply of sodium chloride? Bunge suggests the following ingenious explanation: If a potassium salt, for example, the carbonate, comes in contact with sodium chloride, a partial decomposition takes place, a little potassium chloride and sodium carbonate being formed. Now, as regards the inorganic salts of the blood-serum, sodium chloride ranks foremost. It is found there to a considerable extent, and, as far as we know, the amount is kept fairly constant. On bringing the serum in contact with the abundance of absorbed potassium salts obtained from the vegetable nourishment, this double decomposition between the sodium salt in the blood and the absorbed potassium salt will take place to some extent. In this way potassium chloride is formed, and a part of the sodium of the blood combines with the acid which was previously united with the potassium. By this process the composition of the blood is changed. The serum now contains a substance which did not occur in it previously, or at any rate not to the same extent as now; namely, the newly formed sodium salt. It is the duty of the kidneys, as we shall see later, to keep guard over the serum and to regulate its chemical composition. They eliminate every constituent which, under normal conditions, is foreign to it, and take away any excess of compounds which belong there. In the above case the kidneys eliminate the newly formed sodium salt together with the potassium salt. This process, therefore, results in the serum being deprived of sodium chloride.

"Bunge succeeded in testing this theory experimentally. He, himself, took 18 grams of potassa as phosphate and citrate in three doses during the course of the day, and showed that as a result his body lost 6 grams of sodium chloride. This does not constitute an abnormal amount of potassium salts. A man fed largely on potatoes will easily take 40 grams of potassa into his system during the day. The loss of sodium chloride is by no means restricted to the blood. There is a constant exchange of material between it and the cells. After what we have seen with regard to the effect of the ions, we can easily understand the possibility that a diminution in the amount of sodium contained in the cells, which is in no way replacable by potassium ions, may lead to serious disturbances. The organism, at all events, will attempt as soon as possible to restore the disturbed equilibrium.

"Bunge, to support his views, cited numerous facts. He showed, for example, that in France the country folk consume three times as much salt per capita as those who dwell in cities. Now it is a fact that in the country much larger quantities of vegetables are eaten than in the city, where the diet consists largely of meat. A further support of the assumption that the vegetables rich in potassium were the cause of the increased consumption of salt was gained by the study of people who live entirely upon meat, *e.g.* certain races of hunters, fishermen, and nomads. To gain this knowledge, Bunge read through a large number of articles on travels, and also placed himself in correspondence with travelers. In this way he established the fact that at all times and in all countries where the people subsist solely upon animal nourishment, either they have no knowledge of salts or do not care for it, whereas, in countries in which the inhabitants sub-

sist mainly on vegetables there is always such an unmistakable craving for salt that it has become considered as one of the necessaries of life. This is the case in both the north and south polar regions. Again, in countries in which the inhabitants live on meat and rice there is no craving for salt. Rice contains but one-sixth as much potash as wheat, rye, barley, or Indian corn, one-twentieth as much as the legumes, and from one-twentieth to one-thirtieth as much as potatoes.

"Now what happens in the case of a people subsisting chiefly on vegetables, and yet living where there is no salt supply? Such people prepare a salt of their own. Thus, Bunge was able to procure a salt obtained by ignition of a plant which was used by the negroes in the southern part of Kartum, Africa, as a seasoning for their vegetable food. The analysis of this salt showed it to contain 19.27 per cent. Na_2O and 4.92 per cent. K_2O, or nearly six equivalents of soda to one of potash. It is interesting here to find that the natives have selected a plant, salsola, or salt-wort, which is especially characterized by its high soda content. The natural instinct, however, does not always assert itself so well in this direction, for there are other races which use for salt the ash of a plant rich in potash. Lapicque examined such a salt. The inhabitants of the Angoni district in British Central Africa use a substance prepared by burning goat manure and wood. Analysis showed that it contained 21.98 per cent. KCl and 0.47 per cent. NaCl. It is interesting to learn, however, that after Lapicque had shown the natives how to obtain salt they gave up the preparation of their own native condiment. Salt, for the inhabitants of Angoni, is an extremely expensive article of commerce. The natives toil for salt upon the plantations."

We quote this to show how absolutely necessary salt is to the individual. Is it surprising, therefore, that the value of this mineral when combined with water just as it is in the cell should have a benign influence on pathological conditions? We are firmly convinced that the limit of the influence for good of salt solution has not yet been reached.

Following the discovery by Pasteur and Lister, we acquired the habit of using strong antiseptic solutions, believing, as we did, that a solution which theoretically in the test tube inhibited the growth of bacteria, or killed the bacteria, must of necessity be the ideal solution in suppurative conditions. As time went by and our experience widened and brought with it a more intimate knowledge of the capabilities of the cell to protect the body, we gradually became weaned from this idea and now know that if a solution is strong enough to kill the bacteria it is strong enough to destroy the tissues. The word of the day being simplicity of technique in surgery, supporting nature, wholesome food and fresh air, it would seem that we had arrived at the age of greatest wisdom.

One must conclude that a salt so intimately associated with life and necessary to its existence, has many virtues not possessed by alien drugs.

"Henkel discusses some recent communications on the effect of saline infusion as liable to be injurious, but states that his experience has been the reverse. It seems evident that the animals are affected differently from human beings — all his experiences speak in favor of the harmlessness and possible benefit from salt incorporated in various ways, even when the kidneys are decidedly pathological. Six pregnant women near term were given 10 gm. of salt daily for a month. The urine was examined daily for two weeks and then every third day. In a second group, four pregnant women were given an intravenous injection of 5 c.c. of a 10 per cent. solution, and four others a subcutaneous infusion every third day. In none of the women was there any evidence of injury and albumin never appeared in the urine; except for increased output of urine there did not seem to be any symptom from saline infusion. Another woman with parenchymatous nephritis, but no edema, was given an intravenous injection of 5 gm. of a 50 per cent. solution. The Esbach findings previously had been 4 per cent., but notwithstanding the saline infusion the albuminuria constantly declined and the urine was normal in eight days. In another case of nephritis, with edema during the puerperium, the 4 per 1,000 albuminuria had subsided by the nineteenth day to mere traces. The woman was then given two intravenous injections of the same amount and concentration as the other patient, but all within twenty-four hours, and no harm resulted. The edema did not return and the urine remained normal. In a still more severe case of nephritis with 8 per 1,000 albumin and changes in the retina, subcutaneous infusion of 1 liter of 1.8 per cent. salt solution increased the output of urine, but did not check the progressive subsidence of the albuminuria, which sank to 0.25 per 1,000 by the second day of the puerperium, then 15 gm. of a 10 per cent. salt solution were given at one time. The albuminuria did not increase and the diuresis remained good. In another case a woman at the ninth month of pregnancy, free from albuminuria at any time, and the specific gravity of the urine increased only from 1,017 to 1,020. Weichel has recently reported that a 10 per cent. salt solution kills the bacteria of meat poisoning, and Henkel thinks that this confirms the general impression in regard to the direct disinfectant that can kill bacteria in tissues without injuring the tissues. Many have already witnessed great benefit from saline infusion and the experiences here related supply, he says, the scientific basis for the clinical facts observed. Notwithstanding, therefore, the unfavorable action of salt in experiments on animals, he thinks that there is no reason to refrain from saline infusion in the clinic, not even when there are edema, a heart defect, or nephritis. He has made much use of salt in eclampsia, and has never witnessed harm, but rather benefit."

Henckel's conclusions as to the subject of more concentrated solutions than nine-tenths of 1 per cent. do not seem to be in keeping with physiological facts. It may be that the use of small quantities of concentrated solution may have the virtue of destroying bacteria without causing laking of the blood, but the only experience the writer has had with a concentrated solution terminated almost fatally. It was a case in which an appendicostomy had been done for amebic dysentery. By some mistake the nurse injected into the bowel a concentrated stock solution of salt and, when the writer saw the patient, he was in a state of collapse. The tongue was swollen, and he was exceedingly thirsty; it took several hours to resuscitate him.

Cases have been reported by other men. Hare mentions several cases in which death resulted from the use of solutions more concentrated than the normal, so that it would seem to us care should be exercised before departing from the physiological salt solution. We have had excellent results with the normal salt solutions in amebic dysentery and

in severe infections of the rectum. Five cases of amebic dysentery have been cured by the exclusive use of physiological salt solution and it was this fact that tempted the writer to bring the matter before the profession.

The next case in which this solution has been used is a most interesting one. Mrs. L. R., 39 years, married and the mother of several children. She was perfectly well up to four years ago, when she had an attack of diarrhea, which was ushered in by bearing-down pain in the rectum with an intense desire to move the bowels — so much so that she would sit in the toilet for long periods, straining, without getting much relief. At times the desire to move the bowels became so imperative that she would not have time to reach the toilet and would soil her clothes. At first she had fairly good movements, mixed with blood and mucus. Later, she passed large quantities of blood mixed with mucus. This condition lasted for about a month and gradually abated. Ever since that time her bowels have been irregular. At times she would be comfortable, but from time to time would suffer acute exacerbations. She went along in this way for two years before seeking medical aid, and was then treated by different physicians, who did not examine her but used drugs with indifferent success.

One year ago she was examined at one of the hospitals in New York and was told she had tumors and an operation was advised and consented to. In November, 1909, several tumors were removed by cautery, but she suffered such intense pain after the operation that she did not return for further treatment, considering herself benefited by the operation, but dreading repetition of the pain. In February, 1910, she drifted into my clinic at St. Bartholomew's. She had then lost considerable weight, was very anemic and poorly nourished. The rectum and lower sigmoid were found studded with polypoid sessile growths varying in size from that of grape seed to that of a cherry. The examination also disclosed numerous ulcers of the mucous membrane, their size varying from that of a pin-head to one-half an inch in diameter. The remainder of the membrane was granular, bled easily, and was covered with mucus, blood, and pus. The upper portion of the sigmoid was fairly healthy. The treatment advised consisted of an enema of cold physiological salt solution morning and evening, with an occasional additional injection of 25 per cent. solution of aqueous fluid extract of krameria. She was kept under observation, and still visits the clinic twice each week, the improvement being marked after the first treatment, which occasioned the patient so little inconvenience that she has gladly followed the prescribed course and is regular in reporting. The improvement has been steady. We should mention here that the polypi were removed at several sittings by means of a wire snare. The very small ones were not touched but gradually disappeared. Following the disappearance of all the polypi, the mucous membrane remained in an ulcerative, sloughy condition, the rectum and sigmoid were covered with mucus and pus, and in fact there was very little healthy mucous membrane, but all the polypi had disappeared.

It seemed to us under the circumstances there was nothing to do but a colostomy in order to relieve the strain, after which it was inevitable that this inflammatory condition should go on to a formation of a tubular stricture. Examination of a section of the mucous membrane shows the following condition: Microscopic sections show a small piece of the glandular layer of the mucous membrane arranged about a central stock of dense adult fibrous tissue which is infiltrated to a marked degree by inflammatory, small round cells, fibroblasts, and exudate of leucocytes, among which are a few eosinophiles. The fibrous interstitial tissue between the glands shows in a few places a considerable increase and is infiltrated in these areas by small round cells and leucocytes, one area showing a large accumulation of lymphoid cells, with a tendency to develop centrally fibrous tissue fibrils. The glands appear normal and show no tendency to proliferation.

Diagnosis: Chronic interstitial and acute exudative colitis. December 6, 1910. The patient had now been under our observation one year. About three months ago we put her on injections of physiological salt solution exclusively, about a quart twice daily. She came to the clinic once a week, and we kept her under observation. She was so much improved by this treatment that we decided to abandon all other lines until we had given this adequate trial. The patient was examined January 16, 1911, by the writer, by Dr. Humphries, and also by two of our colleagues, who have been visiting New York, namely Drs. Cleland and Walter McKeown. The inflammatory condition had entirely disappeared, the membranes had a healthy appearance, and the ulcerated condition was healed. We believe this entirely due to the systematic and continuous use of the salt solution.

We have also had very excellent results following the use of Wright's solution in suppurated conditions. Wright's solution is sodium citrate 1 per cent., sodium chloride 4 per cent.

We shall not speak of the many advantages possessed by this solution, as the entire profession are aware by now of the wonderful results obtained in peritonitis by the use of Murphy's method, or proctoclysis. Nor will we dwell at length on the wonderful results obtained by infusion of physiological salt solution, as these miracles are quite well known; but we must say a few words about the administration of this solution when mixed with adrenalin. Some fatalities have recently been reported by the use of adrenalin saline. The cases reported (so far two or three) have been supposed to have been due to some deterioration of the adrenalin.

Haeberlein, in the *Zentralbatt für Chirugie,* November, 1910, reports a case of peritonitis in which intravenous infusion of 100 to 500 c.c. of salt solution, to which eight drops of adrenalin had been added, gave him relief, but was followed an hour later by severe chill and increasing pulse rate and temperature, with death in less than three hours. He explains this as the result of washing out from the lymphatics the accumulated residual toxins. This sudden flooding of the circulating blood with toxins and their absorption readily explained the symptoms in sepsis under the vasoconstrictive action of the adrenalin.

The writer will add two cases to those already reported.

The first case was a case of general sepsis following a colon fistulous infection. The patient was in an almost moribund condition, and it was decided after vaccines and serum had been used to try an in-

travenous infusion of normal salt solution, to which twenty minims of adrenalin had been added. About a minute after the solution had been administered the patient became restless, exceedingly nervous, and frightened. This was followed by a severe chill which lasted five minutes, and in which the patient shook the bed. There was great improvement in the patient's condition following this, apparently, and the writer ascribed it to a possible fresh focus of infection, but did not suspect the adrenalin at the time. It became necessary, a little later, owing to the condition of the patient, to administer another intravenous infusion. The same symptoms followed, and the patient died about four hours afterwards.

The second case was a patient, Mrs. N., who had had a major operation. The first twenty-four hours following the operation she passed only two ounces of urine. All methods to stimulate the kidneys failed. It was decided, therefore, to give an intravenous infusion. Ten minims of adrenalin were added to the solution. About fifteen minutes later the patient had a violent chill, became excited, and died one hour afterwards. Both of these patients would inevitably have died within a short time, one owing to septic condition, and the other to the shutting down of the kidneys; but we are inclined to think that there is no question but that the adrenalin saline had something to do with hastening the end. Whether the condition was due to washing out from the lymphatics the residual toxins or to some other condition we cannot say, but we bring up these cases that in future great care may be exercised with this preparation under the circumstances we have mentioned.

58 West Fifty-eighth Street.

WHAT CONSTITUTES HYPERCHLORHYDRIA?*

By CHARLES SUMNER FISCHER, Ph.D., M.D.

NEW YORK.

The frequency with which excessive native acidity is encountered in the ordinary dyspepsia of everyday life has rendered the term hyperchlorhydria almost a synonym for chronic dyspepsia. To question this frequency would seem heretical according to accepted standards. For the close observer, however, there is both clinical and physiological justification for some doubt. In a previous article I have attempted to show that the hypersecretion of hydrochloric acid by the stomach is an entirely physiological process inherent in the organ as a result of biological development, hereditary inducement, and established habit. A normal stomach must respond to a physicochemical or psychoneurotic insult by an overproduction of its customary secretion in a defensive sense if in no other. This attitude in itself would account for the great frequency of this condition, for every beginning dyspepsia must be hyperacid unless there exist constitutional reasons to the contrary. Hence, the average gastric analysis as ordinarily practised will reveal the condition hyperchlorhydria in a majority of all chronic stomach diseases and the term has become a byword in gastrology.

It is a question whether the standards heretofore accepted as indicating this condition will not have to be modified. Viewed from the biological standpoint, the apparently excessive secretion of hydrochloric acid cannot always be regarded as a pathological process in the absolute sense. No physiological activity, called into being for natural reasons, can be so regarded. The ulterior consequences may be unfortunate, but the motive remains normal. The ultimate effects are purely individual, and depend on physiological and psychological adaptivity. Clinical experience teaches that many people constantly exhibit and support a high degree of natural gastric acidity without symptoms. It is also a matter of common observation that the disappearance of existing disagreeable symptoms does not always depend upon fluctuation of the acid content of the stomach. The examination of many cases, months and years after relief through medical or surgical measures, will reveal the percentage composition of the gastric secretion unchanged. To such an extent is this true that the possibility of influencing an established and habitual gastric secretion, except in distinctly anatomical abnormalities, becomes entirely problematical, at least, within the usual observatory periods of time. Symptoms may be relieved, but inherent vagaries remain, and the whole object of treatment in many of these cases would seem to be to adapt the organism, mental and physical, to local conditions as they exist.

To those to whom the mellowing effect of clinical experience, as opposed to more accurate laboratory data, does not appeal, who demand more convincing scientific evidence, it can be suggested that the most recent physiological research seems to be supplying the same. From this it would appear that the normal percentage of hydrochloric acid in the average stomach is higher than formerly supposed. With improved methods of experimentation it would appear that what has heretofore been accepted clinically as the hyperchlorhydric state represents, in reality, a normal secretion. We have been in the habit, in the past, of classifying as hyperchlorhydria all cases in which the free natural acid content of the filtered chyme reached two and one-half to three per thousand. With this quantity of free acid the usual symptoms should appear. The physiologists now tell us that the normal gastric juice always contains hydrochloric acid to the extent of five per thousand. According to the old conception, any stomach exhibiting this new value would find itself in the hyperchlorhydric state and should respond antagonistically to its normal secretion. On this account certain authorities would disclaim the existence of hyperchlorhydria as such. On the other hand, there are those who contend that a food-containing stomach should never exhibit the physiological limit, chemically demonstrable as free acid, of hydrochloric acid. Granted that the stomach always secretes acid in excess of requirement, 50 c.c. of a trial breakfast should call forth a secretion to assure this excess; that is, a certain volume of secretion with a certain percentage of hydrochloric acid, which, according to the latest developments, is five per thousand. In a careful adjustment of volume to volume of secretion and test meal the excess of acid should always be a constant factor. Fifty c.c. of a test meal of given neutralizing capacity and 50 c.c. of secretion of five per thousand hydrocloric acid content should give the necessary moderate excess of acid. If, however, the neutralizing capacity of the test meal be reduced for any reason, the excess of acid must increase proportionately, so that with a hydrochloric acid content of the normal secretion of five per thousand a hyperchlorhydria may be diagnosed

*From a paper read before the Associated Physicians of Montclair, N. J., and vicinity, December 19, 1910.

when, in reality, it does not exist. Indeed, any stomach secreting a juice even in slight excess of its neutralization requirement should exhibit the condition hyperchlorhydria. This would explain the existence of many cases of so-called hyperchlorhydria without symptoms. These individuals are merely supporting a normal gastric juice. This would further limit the diagnosis of hyperchlorhydria to those cases where the volume of secretion is small but the percentage of acid is very high. This number is exceedingly limited, for volume and acid percentage as a rule go hand in hand. Hyperchlorhydria gastric contents are usually very fluid and achylias exhibit the opposite characteristic. A decided differential secretion of acid, ferment and fluid in the digestive secretions has yet to be demonstrated.

The average acidity of a given stomach depends broadly upon four factors. These are the quality of the contained food, its quantity, the rapidity of discharge into the duodenum, and the secreting capability of the organ. The first two are variable quantities. The last two are more or less fixed for each individual. The quality of the ingesta as a factor in digestion is more important experimentally than clinically. The results obtained for the acid secretion by differential food stimulation upon esophagotomized dogs cannot be applied directly or practically to man. In the latter many uncontrollable influences would tend to vitiate such results. The tremendous importance of the psychological element in man's digestion cannot be too fully realized. All the various attempts to permanently influence the gastric secretion in the human subject in the past by persistent application of dietetic methods, based upon the proteid, carbohydrate, and fat content of the food, have been failures. The uninterrupted administration of any one of these elements over a period of time will usually produce the opposite to the desired effect. The stimulating property of the proteids to the gastric secretion, when they are given exclusively, diminishes in power in a certain relation to the time of administration. Clinically we know that many chronic dyspeptics of a certain type do badly on a monotonous diet. This is due to the fact that the majority of the ordinary cases are the result of conditions and environment rather than specific indiscretions. Abuse of the stomach is an overrated conception. Under normal general conditions the average stomach is able to withstand the ordinary unavoidable assaults of daily life. The specific, monotonous, scientifically considered dietary of the books usually does more harm than good. It is folly to expect benefit from a régime which makes life more miserable than it was before. The result may be physiological and phychological rebellion.

Constitutionally each living organism requires so much food of proper chemical constituency for its maintenance. Physiologically there should exist a certain relationship as to time and quantity between the gastric juice and the ingested food, in which case the acidity of the stomach should be more or less of a fixed quantity for a given period of digestion. While the number of required calories is established by natural laws, the method and time of their administration are established by individual habits and the secretion of gastric juice is regulated by the latter. If the habits of the individual are such that the daily food requirement is administered at regular intervals in adjusted quantities of proper chemical proportion, the excess of acid found upon examination will be normal. If, however, the exigencies of daily life necessitate an unequal and irregular distribution in the sense of insufficient or excessive quantity at certain periods of the day, there may be established a habit of secretion adapted to the one or the other. Either the quantity of secretion is sufficient for the smaller quantity of food and insufficient for the larger, or *vice versa*. Judging from the natural tendency of the normal stomach to oversecrete, it is fair to assume the organ will adopt a quantitative habit of secretion adapted to the greatest timely requirements. In this manner the possibility for hypersecretion after small quantities of food always exists, and to these latter the ordinary test meals belong. On this account we often find the hyperchlorhydric state after such tests when, in reality, it does not exist. They have simply called forth the habitual secretion of the individual. This does not indicate that the quantity secreted is not adapted to requirements. It would rather indicate that the tests have failed to meet such requirements and have led to fictitious valuations.

The rate of discharge of food into the intestine has an important bearing upon gastric acidity. Many cases of secretory disturbance are, in reality, affections of motility. Physiologically, the empty stomach should contain no acid or very little acid mucus. In an individual of well regulated habits this normal condition prevails. Clinically, however, the great majority represent two classes—namely, those whose stomachs are never really empty and those whose stomachs are empty most of the day, that is, up to the principal evening meal. The latter class is a numerous one, due in part to compulsory habits of diet, in part to causes over which there is no control. It is an incontestable fact that the remote constitutional influences represented in the lack of inhibitory control, which are the foundation for many cases of hyperchlorhydria, are associated with hypermotility. The motor functions of the stomach are affected similarly to the secretory functions. This association is the best possible combination for hypersecretion and is found in many cases of dyspepsia during the early stages. Examination at this time will often reveal hyperacidity, at least, a very high degree of acidity, which according to accepted standards passes for hyperchlorhydria.

In judging the acidity of a given stomach it is necessary to determine, if possible, what constitutes abnormality for that particular individual. It is reasonable to suppose that each individual possesses an acidity of his own to a certain degree. What is normal for one will not be so for another. We have been in the habit of placing a certain range limit upon the free hydrochloric acid in the stomach. Anything beyond these limits is considered abnormal. According to the newer physiology, these limits will have to be considerably widened. Aside from this, however, there can be no doubt that each individual possesses a characteristic secretion of his own, called into existence by habit, environment, and constitutional requirement. It is the deviation from such acquired acidity, suitable for the purposes of digestion of the individual, which constitutes abnormality. Many individuals, apparently normal, at least comfortable, continuously exhibit an achylic state. Given ten cases of so-called hyperchlorhydria and the symptoms will vary considerably. A certain percentage will give no symptoms whatever. This cannot be demonstrated in a clinic. Here only individuals with symptoms present them-

selves. It can only be demonstrated by examining apparently normal cases.

These differences in susceptibility have heretofore been explained by variation in local irritability. To a certain extent this is true. It is not a universal explanation, however. It simply proves that a certain degree of gastric acidity is excessive for that particular individual for the time being. His hyperchlorhydria may have existed all along. The individual receptivity changes, not the acidity. The latter had been fixed long before by predisposition, determining habits, and general adaptivity. If high, as a result of these influences, the other digestive secretions have been so regulated as to insure a harmonious action of the whole. Hence, apparent hyperchlorhydria may not only be frequent, but its diagnosis becomes entirely an individual matter. The simple determination of the composition of the gastric contents by the usual tests does not constitute a diagnosis. Such examinations reveal a certain degree of acidity, the actual physiological or pathological significance of which must be determined by an intelligent interpretation of all the personal factors in a given case.

The diagnosis of acid conditions in the stomach by the usual methods of tube extraction is based upon the supposition that the material obtained for analysis represents part of a homogeneous mass, any part of which would give a percentage composition characteristic of the entire contents. It is assumed that the invading food is rapidly reduced to a homogeneous state by active muscular action, so that it is immaterial from which part of the stomach the material for examination is taken. The truth of this depends somewhat upon the consistency of the food test. If the same is in fairly liquid form, it is probable that a comparatively rapid combination occurs. If, however, the test is more or less solid, contains proteids in quantity, and does not readily leave the stomach, the conditions are changed. Under the latter circumstances the average and promiscuous analysis may give false values.

Before deciding upon the existence of a hyperchlorhydria it is always wise to determine the state of motility. In case the latter is increased a hyperchlorhydria can easily be diagnosed, when, in reality, it does not exist. The motility is always of first importance in this connection. Especially is this the case in its relation to the consistency of the applied test meal. The most recent investigations would seem to indicate that the fundus of the stomach exhibits very little muscular activity. Certainly, there is no decided churning of the contents. There is a slight pendulous motion to the whole organ and a tonic contraction of the muscular structures around the contained food, which gradually relaxes in proportion to the quantity of the latter. In this manner the more solid portions are held in place for the action of the liquefying gastric juice. This liquefaction takes place only upon the surface of the bolus and the fluid portions resulting pass on to the antrum, where active muscular contraction injects them into the duodenum. Hence, it appears that, in the case of food of some consistency, the gastric secretion does not penetrate to the center of the mass. In the case of more liquid tests, such as the Sahli emulsion soup, the inactivity of the fundus favors a separation of the fat from the rest of the fluid and observation of a bismuth test contents *in situ* reveals three distinct layers, with the heaviest or bismuth-containing portion at the bottom, thus vitiating, to a great extent, the value of these methods for diagnostic purposes.

It is evident that such conditions must have some bearing upon the value of the average analysis of gastric contents as ordinarily practised. The analytical findings will depend, to a great extent, upon the position of the end of the tube in the cavity of the stomach. If the tube is soft and passes over the surface of the food bolus, between it and the mucous membrane, the extraction will represent the gastric secretion in purer form than if it possesses sufficient consistency to penetrate to the center of the mass. With a physiological secretion of five per thousand it is evident that the differences might be very appreciable. The depth to which the tube penetrates is also important by giving misleading values for fundus and antrumacity. It is only under certain conditions that these possibilities may be considered. They demand primarily a gastric content of a certain consistency and a musculature capable of a certain contractile power. These conditions exist many times, however, and are especially important in all tests which approach in consistency those of average daily meals. It is also evident that these considerations can only apply to cases in which the gastric acidity is normal and excessive. They can have no bearing upon achylia or subacidity.

In a rough way, these facts can be demonstrated by giving a test meal composed of a cup of tea, slice of bread, and a quarter of a pound of chopped beef, and making two extractions at the end of two hours. The first should be made by passing the tube until the contents appear by aspiration, preferably near the cardiac orifice. The second is taken by passing the tube to its limit. The analysis of the two extractions will often show a difference of ten to twenty degrees for the free acid, with a total acidity more or less constant. If such differences appear upon the employment of crude clinical methods, it is very probable that by a finer adjustment of the manipulations still greater discrepancies could be elicited. It is quite evident that the gastric contents do not constitute a homogeneous mass and that the position of the end of the extracting tube in the cavity of the stomach deserves some consideration. Should it so happen that the contents extracted consist of gastric secretion which has not come into intimate contact with the food from a point close to the surface of the mucous membrane, analytical figures may be obtained which, to all intents and purposes, would be hyperchlorhydric, whereas, in reality, they represent only pure gastric juice.

The simple determination of gastric acidity is not sufficient for diagnostic purposes. The apparent frequency of hyperchlorhydria is due to a lack of consideration of the various mechanical and personal factors in each case. Only when these harmonize with the analytical findings can such a diagnosis be made.

144 East Thirty-eighth Street.

THE *X*-RAY AS A CURATIVE AGENT IN MALIGNANT TUMORS.*

By ASPINWALL JUDD, M.D.,

NEW YORK,

ADJUNCT PROFESSOR OF SURGERY AND FORMER RADIOLOGIST OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In taking up the therapeutic application of the *x*-ray to cancer it will be my aim to point out as clearly as possible the physiological action of the ray, and allow the auditor to make his own application to

*Read before the Radiological Society at the New York Academy of Medicine, February, 1911.

the particular diseased condition. Indeed, in the space that I am able to devote to this paper it is impossible to go into the details of the treatment of the various conditions in which this agent has proved of value. In addition to the above I shall give only such examples as may more fully emphasize my point. The best electrotherapist is the one who treats each case with a proper regard to the varying conditions which arise, remembering that individual idiosyncrasies to the rays are just as marked as idiosyncrasies toward drugs, and that a stated dose which will always hold good can no more be prescribed in the use of electrical agencies than in drugs. The *x*-ray is not a cure-all. Indeed, in many cases, even where it has therapeutic value, other agencies are preferable, both medical and surgical. On the other hand, there are certain diseased conditions in which by its means our results are incomparably better than by any other means at our disposal. It should be the aim of the electrotherapist to carefully separate the wheat from the chaff and to bring the science to a new dignity by a careful choice in his treatment of cases, rather than by extravagant claims to make it the object of skepticism and ridicule, as is too often done.

In our study of the *x*-ray it is well that we should bear in mind at the outset the character of the agents with which we have to deal and what it is that we are endeavoring to do with those agents in order to produce the proper effect upon our tissues. With this end in view an understanding of the physiological action is essential. We have then the cathode stream and the *x*-ray.

The physiological action of the cathode stream in a low tube is merely that of sunlight intensified, producing, first, hyperemia, and, if carried to its fullest extent, escharosis. It does not penetrate beyond 6 mm. from the surface of the skin, consequently is valueless in treating the deeper structures of the body. A low tube being rich in the cathode stream is of use only in treating skin or surface conditions.

The x-ray in a high tube penetrates all substances with a velocity proportional to their density, travels in straight lines, has a selective action upon diseased tissue, and its effect is, first, to produce stimulation. Upon cell growth this stimulation produces a proliferation of cell elements by division of the nuclei and the formation of new cells. When this effect is intensified it produces overstimulation, with destruction of the cell through fatty degeneration or necrosis. Upon blood-vessels this destruction of the intima or endothelial lining produces a curling up of the membrane, a plugging of the vessel with cells, an increase in fibrin, and finally an obliterating endarteritis. Upon connective tissue the stimulation produces an exaggerated adult type of connective tissue, *i.e.*, fibrous tissue, this by the growth of cells, changing them into fibers with obliteration of the nuclei. Its effect upon epithelial tissue upon the surface of the body is to produce a necrosis and slough of the tumor. Upon deep-seated epithelial growths its first effect alone is apparent, the end result being an increase in the growth of the tumor with the more rapid formation of metastases. Upon connective tissue growths, *i.e.*, first, sarcoma, its effect is to change the embryonal type of connective tissue into the adult type, transforming the sarcoma into a fibroma; secondly, by producing an obliterating endarteritis, to deprive the growth of a part of its nourishment, the end result being a fibroma with nests of sarcoma cells included within it. After a certain time these cells resume their growth, with a consequent recurrence of the sarcoma, which, however, reacts to the ray as kindly as before. The weak point in our use of this agent in this class of cases is our inability to prevent the formation of metastases. The effect of the ray upon fibromata is simply to increase their growth through a proliferation of the fibers. Upon glandular tissue its final action, by overstimulation, is to produce a death of the cell elements. This applies to all glandular tissue, adrenals, thymus, thyroid, lymphatics, liver, spleen, kidney, etc. Upon the leucocytes its action is first, by the division of the cells, to produce an increase, and then, by overstimulation, a rapid diminution in their number. This applies in less measure to the red cells, producing anemia.

Toxic Action.—By destruction of the cell elements and consequent liberation of nucleins the *x*-ray produces a rapid accumulation of toxins. Unless this is carefully watched in the class of tissues which easily break down a degree of autointoxication resulting fatally can readily occur.

X-Ray Burns.—*X*-ray burns are probably produced by the action of the cathode stream producing *x*-rays at the surface of the tube, and, to a much less extent, of the penetrating *x*-rays upon the tissues of the body. They develop very slowly. Three weeks from the time of the initial exposure is usually required for their appearance. They go on growing deeper by the destruction of tissue and obliterating endarteritis, are very painful, and cannot be controlled by any known agent. The treatment of *x*-ray burns is extremely unsatisfactory. The use of a soothing ointment, orthoform in lanolin, in saturated solution, has yielded the best results, in my hands.

As the effect of the *x*-ray is to produce, first, an increase, and, secondly, a diminution in the number of red cells, we should carefully look out for and treat the anemia resulting from our use of the ray.

The treatment of carcinoma naturally divides itself, first into the treatment of superficial carcinoma or epithelioma; secondly, of deep-seated carcinoma.

Epithelioma.—There is no class of cases amenable to the *x*-ray that has yielded such brilliant results as those of superficial epithelioma. About 90 per cent. of these cases, in which the growth is confined to the surface of the body, *i.e.* without metastases or glandular involvement can be cured by this means. Where, however, glandular involvement has occurred, unless the glands are very near the surface of the body, the chance of a successful issue is very small. This conclusion has been arrived at after the treatment of a large number of cases extending over a series of years, and in spite of the opinion expressed by some authorities. In about 10 per cent. of cases, especially growths occurring in old people and in which the growth contains considerable numbers of nests of pearl cells, *i.e.* keratoses, the *x*-ray, while it causes destruction of the growth, fails to prevent its almost immediate recurrence. In the treatment of epithelioma the operator should not be discouraged if his patient fails to react easily, but, with patience and a suitable dosage, he can rest assured of the total disappearance of his growth and of a resulting smooth white cicatrix. In this class of cases we have the choice of a low tube, or a high tube, one rich in penetrating *x*-rays. As the growth to

be treated is on or near the surface of the skin, and as the low tube is efficient in these localities, and as, moreover, the energy or quantity of current required to excite such a tube is much less and the consequent expenditure less, the low tube will probably be preferred. In treating a case of this sort the patient should be thoroughly protected, leaving exposed the growth and about one inch of sound, surrounding tissue. This is for the purpose of eliminating any wandering cancer cells, which may be present in apparently healthy tissue. The tube should be focussed directly upon the tumor. The distance of the tube from the patient depends somewhat upon the tube we are using —with a low tube, a short distance, an inch and a half to six inches; with a high tube, sometimes as great a distance as nine inches. If it is our desire to rapidly affect the growth, the tube will be placed a short distance from the patient, remembering that in this way we will probably get the escharotic effect with the production of a considerable burn. We must warn the operator not to produce too deep a burn, as in such cases an ugly scar will result. In the average case, possibly six inches will be the ideal initial distance, the tube at a later date being placed closer to, or drawn farther away from, the tumor, depending upon the idiosyncrasy of the patient.

We have two quantitative methods of treatment at our disposal. The first consists of giving huge doses, fairly overwhelming the tumor, using twenty to thirty-five minutes at each exposure, the exposures being relatively far apart. This method is not recommended by the writer. The other method consists of starting with ten minutes' exposure two or three times a week, increasing the length of exposure and decreasing the distance of the tube from the tumor if the growth proves resistant to treatment. Do not be discouraged if no result is apparent, even at the end of three months' exposure. When the tumor begins to react the destruction will be rapid. It seems entirely unnecessary to cite illustrative cases of cure in this condition. If any one fact in the therapeutic application of the *x*-ray has been established beyond doubt, it is that superficial epithelial growths are absolutely curable in more than 90 per cent. of all cases by this means.

Malignant Angiomata.—This condition, being a superficial epithelial or endothelial degeneration, reacts most favorably to the action of the *x*-ray. In fact, the condition is easier of control in the early stages than any form of neoplasm. The obliterating endarteritis set up by the ray not only deprives the growth of its nourishment, but destroys it as well. The end result from a cosmetic standpoint is very good indeed. In this class of work a high tube should be used, care being exercised not under any circumstances to burn what is always an extremely delicate skin. One case, by way of illustration, is appended.

Case I.—A baby fifteen months of age was referred to me by Dr. John Erdman. An operation four months previously had been undertaken for the removal of the growth, which occupied the right temporal region, extending down on the cheek. The condition had promptly returned, and, when I saw the case, was irregular in outline, about an inch and a half wide by four inches in length, deep purple and growing rapidly. During the early treatments chloroform had to be administered to keep the little patient quiet. Careful protection by means of lead foil was afforded, a very high picture tube being used. The treatments varied from five to eight minutes in length, distance of tube from patient in this particular case never closer than fourteen inches—treatment twice a week on the average. The condition began to improve within three weeks, and within three months had entirely disappeared. This is nearly three years ago. At last report patient remained cured with no remaining sign of the trouble, even the scar of the surgical procedure being scarcely perceptible. It is worthy of note that not even tanning of the skin occurred at any time. Indeed, with our present knowledge and proper care, burning of the skin or deeper tissues is entirely unjustifiable, except in those cases where, for proper reason, we deliberately aim at this result.

Deep-Seated Carcinoma.—In my opinion, the only class of cases in which the *x*-ray is justifiable are those of a thoroughly inoperable character where an alleviation of pain occurs after the use of the ray. This happens in about 80 per cent. of cases, and, if the result at which we aim is merely euthanasia, this treatment is preferable to opium or other analgesics. We must prepare ourselves, however, for the more rapid occurrence of metastases and the earlier death of our patient. In about 20 per cent. of cases the pain is increasesd after the treatments. Where this occurs the *x*-ray is inadvisable. The use of the *x*-ray in any primary, deep-seated carcinoma of the operable stage is, in my judgment, unjustifiable. As will be seen by reference to its physiological action, the ray penetrates with a velocity proportional to the density of the tissue. Its first effect is to produce, by stimulation, an increased growth; secondly, by oversimulation, a death of the cell elements, and, by the production also of an obliterating endarteritis, the death of the tumor. When, therefore, we are able to produce this secondary effect, the ray is efficient Where only the first effect can be produced we are simply increasing our tumor and adding to the danger of metastases. In nearly all the cases that have come under my observation in the last ten years, treated both by myself and by others (and these number nearly two hundred cases), death has been the inevitable result of the treatment of deep-seated carcinoma of primary origin by the *x*-ray, only the first or stimulating effect being apparent. In a number of cases first rayed and afterward operated upon by myself, in which careful and abundant sections have been made and studied, no efficient effect has been found in the tumor. The examination of the enlarged glands has resulted in finding two sorts of glands—first, those the seat of malignant degeneration. On these glands the rays had no effect. In the second class, where the glands were found affected with non-malignant inflammation, a reduction in size or elimination of the glandular structure had taken place. This last is in line with the results of all observers; that is, that glandular tissue not the seat of malignant, carcinomatous degeneration can be entirely destroyed by the application of the ray.

The postoperative raying of malignant conditions I thoroughly approve, and this as soon as healing is complete. In the cases where it is assumed that the entire neoplasm has not been removed we should begin treatment immediately, if possible. I feel convinced that many recurrences can be prevented by this means, and in the instances where cancer cells have been left behind, but by

reason of the operation are brought nearer the field of action of the ray, the chances of destroying these cells and aiding the surgeon in finally completing a cure are very good indeed. It goes without saying that recurrences in the scar are as easy to control as superficial epithelial growths of primary origin.

Treatment of Sarcoma.—In the treatment of sarcoma we are dealing with an entirely different histological or pathological type of tissue. The sarcoma resembles embryonal connective tissue, being rich in cells of round or spindle shape with a loose reticulum of fibers. Coming now to the application of our principle already mentioned, that the effect of the ray is to stimulate cell growth, the effect upon sarcoma will naturally be the production of an adult type of connective tissue, that is, one rich in fibers, packed closely together, with few cells. The stimulation effected by the ray changes over the embryonal type of connective tissue into the adult type, changing a sarcoma into a fibroma. It also, by the production of an obliterating endarteritis, deprives the growth of a certain amount of its nourishment. The contraction of the growth also tends to reduce its vascularity, the end product being a fibroma with an inclusion of nests of sarcoma cells within its mass. In determining whether we shall treat a sarcoma with the *x*-ray the operability of the tumor comes into question. In these cases the writer strongly recommends its elimination by means of surgical procedure in all possible cases. Where we have an inoperable sarcoma, however, we are justified in the use of the ray. We have been fortunate in being able to cause a disappearance of about 40 per cent. of these tumors.

Recurrence.—It is, unfortunately, true that nearly all these cases recur after a time. The nests of cells included in the mass take on renewed energy, and it is essential that a second series of treatments be instituted. These recurrences react, however, just as kindly, in many cases, as the initial tumor. I have personally rayed a number of second and third recurrences with satisfactory results, and in one case I was compelled to treat the tumor for the fifth time. This case is now of six years' standing, and at the present time shows no sign of further recurrence. It must be remembered of these cases that we never get a complete disappearance of our mass. A fibroma of an extent proportional to the original tumor always remains. Where we can do so, it is advisable, after raying these cases, to enucleate the remaining mass. It must also be borne in mind that the danger of metastases is always present while our patient is undergoing treatment. In melanotic sarcoma this is a very grave danger; in spindle-celled, round-celled, and fibrosarcoma, proportionately less; and in osteosarcoma, still less. Osteosarcoma is more resistant to the action of the ray than any other type with which we have had to deal.

Details of Treatment.—If we are dealing with a deep-seated tumor of any type we must select a tube with the greatest penetration possible, *i.e.* a high tube with a large number of penetrating *x*-rays. The patient should be protected except for the parts to be rayed. As it is essential, owing to the location of the growth, that a larger area should be exposed, our protection is necessarily less complete than in superficial conditions. The tube is best placed at a distance of nine to twelve inches in the beginning, the exposures starting with ten minutes application two or three times a week, with an increase in the length of exposures and decrease in the distance, if it is deemed necessary after the idiosyncrasy of the patient is determined. These cases react very slowly, the treatment often extending over months. In one case four months was required before any effect was shown, and ten months before the final cicatrization of the mass. We must not fail to keep in mind the fact that a severe burn, in treating these cases, will produce a rapid increase in our growth and a rapid dissemination of metastases. In our earlier treatment I lost a case of osteosarcoma of the tibia in its third recurrence by failure to observe proper precautions, a severe burn going on to a spectacular growth of the tumor with metastases, resulting in death.

The case to which I have already referred, in which I was compelled to treat a tumor for the fifth time, is possibly worthy of capitulation.

Case II.—This case, referred to me by Dr. Robert T. Morris, was a woman, thirty-eight years of age, with a sarcoma of the neck. Operation had been attempted and abandoned, owing to the extensive involvement. Such portions were removed as could be taken out without producing disfigurement. This was one of the early cases in which I used a very high picture tube for purposes of treatment. The patient proved extremely resistant to the destructive action of the ray, both upon the skin and deeper structures. Sixty treatments, commencing with one each week and finally going on to three within the same period of time, the exposures lasting for fifteen minutes, the distance of patient from the tube eight inches, finally produced a disappearance of all but a small, fibrous mass situated at the angle of the jaw. The patient then went abroad and remained for a year, when, recurrences having begun, she returned and was subjected to twenty-eight treatments, the method of administration being the same as on the first occasion and the result proving equally satisfactory. At intervals varying from nine months to two years three other recurrences, much less in extent, have taken place; but the result of our treatment has been equally happy in each instance. For the past two years there has been no recurrence. I saw this patient only one month ago. There is no disfigurement nor sign of neoplasm. A small, fibrous, irregularly shaped nodule alone remains. The patient's health is perfect and there are no evidences of metastases.

Case III.—One more instance I should like to note. This case, a man forty-five years of age, a powerful German, was referred to us eight years ago for operation. Upon examination I found a tumor situated in the left side of the abdomen, apparently springing from the ilium, nearly as large as a cocoanut. He was markedly cachectic, much emaciated, and suffering from intestinal obstruction, the last symptom being the cause of his admission to the hospital. An exploratory laparotomy disclosed an inoperable osteosarcoma. The pathological findings corroborated our clinical diagnosis. The patient was immediately subjected to the *x*-ray even before primary union had taken place. The technique was that already described. Within four months the mass had shrunken to the size of an orange, the man had gained forty pounds in weight, and was once more following his vocation of a mail wagon driver. His bowels were normal, and he seemed perfectly recovered. He refused an operation for the enucleation of the remaining mass.

About one year later he returned with a neoplasm about the size of a grape fruit and announced that it had been rapidly growing for the preceding two months. Treatment for three months again caused a shrinkage of the mass to its former size. Two years later a third recurrence took place. On this occasion, being warned by his previous experience, he came to me while the mass was still small. This time I gave him forty-five treatments, with the result of reducing the tumor to the size of a large plum. At the present time (three months ago), when this patient was seen by the doctor who has had him in charge for the past five years, there was no further recurrence and the man was in perfect health.

Lymphosarcoma.—Before closing a word in regard to this condition is indicated. By reference to the changes which we have shown to take place in sarcoma and epithelioma it will readily be realized that, in this condition, we have at once a type of malignant growth in which the *x*-ray is peculiarly efficacious. At the same time metastases are more apt to occur than in any other type of sarcoma while under treatment, these metastases frequently going on to the fatal termination of the case. It will, therefore, readily be seen that early and energetic treatment is indicated if we are to hope for a favorable issue. One example only will be given of this condition.

Case IV.—A young woman, twenty-one years of age, was referred to me with a pronounced glandular involvement, involving all of the cervical, supraclavicular, many of the mediastinal, axillary, and inguinal glands. The retroperitoneal glands were also palpable. Excision of a gland was performed and the pathologist, Dr. Harry Brooks of the Post-Graduate Hospital, made a diagnosis of lymphosarcoma. Six weeks' treatment of this case, with the technique already sufficiently described, produced a diminution of more than one-half in the size of all the glands involved, the various localities being successively rayed in treatments of twenty minutes' exposure each. At the end of this time it was necessary to suspend treatment, owing to the evident toxemia which the rapid breaking down of the glands was producing. In two months' treatment was again resumed, and at the end of five months, greater care being taken not to break down tissue too rapidly, a total disappearance of the glands recurred. This case remained without recurrence for two years, when the patient was lost sight of. There is, of course, a close analogy in the method of treatment and in the results produced in lymphosarcoma and in Hodgkin's disease. The conditions are sufficiently parallel to make the treatment and the results obtained equally applicable.

THE RELATION OF ADENOIDS AND HYPERTROPHIED TONSILS TO RETARDED MENTAL AND PHYSICAL DEVELOPMENT.

By E. BOSWORTH McCREADY, M.D.,

PITTSBURGH, PA.

MEDICAL DIRECTOR, HOSPITAL SCHOOL FOR BACKWARD CHILDREN.

Hypertrophy of the faucial tonsils and of the adenoid tissue situated in the nasopharynx has long been recognized as an important predisposing and causative factor in the etiology of many of the pathological conditions of infancy and childhood. To estimate the relationship which adenoids and hypertrophied tonsils bear to retardation, physical and mental, it is necessary first to consider the pathological physical conditions which make their occurrence possible, and, second, to consider their effect upon growth after development.

Conditions predisposing to tonsil and adenoid hypertrophy. In a paper read before the Pennsylvania Medical Society last October[1] I discussed at some length the characteristics of hypoplasia as shown by the child who is subject to hypertrophy of the faucial and pharyngeal tonsil. This hypoplasia is, in the majority of cases, dependent upon some condition primarily inherent in the ovum, though it may be due to the effect of environmental conditions arising at any time after the beginning of somatic life. We must first, then, look to the parents for manifestations of conditions having a vitiating influence upon cell activity, as tuberculosis, syphilis, cancer, plumbism, malaria, alcoholism, drug habits, insanity, goiter, malnutrition, and environmental influences of various kinds. Given any of the conditions named above in the progenitors, it is very likely that the descendant will be lacking in some of the elements necessary for proper development—will be hypoplastic. This phase of the subject involves the law of degeneracy as advanced by Noble.[2]

That enlarged tonsils and adenoids usually occur in individuals presenting what might be called special diatheses has been commented upon by many observers. Noble says:[3] "Is not this the same pathologic condition (cell hypoplasia) found in the throat and called adenoids and diseased tonsils, and does not this theory explain this group of debilitated women, and also all the children who are not vigorous and who get adenoids and diseased tonsils and become mouth-breathers?" Williams[4] finds adenoids and enlarged tonsils common in children exhibiting symptoms of hypoplasia, due in his opinion to thyroid insufficiency. He believes that adenoids and hypertrophied tonsils are compensatory in their action, correcting, as it were, the thyroid insufficiency. Citelli states:[5] "It is not probable that the tonsils belong to the so-called organs for internal secretion, but in view of certain general or secondary disturbances which are found in adenoid-bearing subjects, which often disappear after an operation, and more especially on account of anatomic researches, I believe it probable that the hypertrophy of the tonsil alone can determine, first, the functional, and then the anatomic, alterations of the pharynx and central hypophysis." Children with pathological conditions of the faucial and pharyngeal tonsils are often subject to the diathesis known as the "status lymphaticus," in which there is a general enlargement of the lymphatic structures associated with hyperplasia of the thymus gland and hypoplasia of the circulatory apparatus. Hypoplasia of the circulatory apparatus is found in chlorotic subjects, who usually present other symptoms of defective development, including hypertrophied tonsils and adenoids.

The diagnosis of the diathesis predisposing to hypertrophy of the lymphoid tissues becomes the same as that of hypoplasia. Among the early symptoms to be noticed are delay in the power of walking and talking, late closing of the fontanels, etc. Progress in these respects may, however, be entirely normal, even more rapid than normal; the precocious child is often an hypoplastic one. Among the most prominent early signs is enuresis,

nocturnal or diurnal. In fact, I have come to consider enuresis, especially when persisting late into childhood, as a most valuable aid to the recognition of this condition. The high-arched palate, first attributed to defective osseous development, and later considered as the result of the presence of adenoids, seems to be again taking its place among the symptoms of hypoplasia, the stigmata of degeneracy. Noble places it among the signs of the condition most easily recognized. Variations in temperature, which may be either subnormal or above normal and subject to fluctuation from slight causes, are not unusual. A constant hyperpyrexia is likely to be due to infected tonsils and adenoids. J. Homer McCready[6] states "that probably one-third of all cases of diseased tonsils and adenoids have a more or less continuous elevation of temperature." Children presenting symptoms of hypoplasia are likely to be undersize and underweight, though they are often tall and slender and often obese, or at least well supplied with subcutaneous fat—the lymphatic type. Graves[7] finds the scaphoid scapula to be common in the type of cases which I would call hypoplastic. In forty-seven cases the children, reported to be much behind in their school grades, were all undersize, showed various anomalies in development, 58 per cent. were mouth breathers, 17 per cent. were subject to enuresis and 85 per cent. showed the scaphoid scapula. Since the appearance of Dr. Graves' paper I have been able to demonstrate the scaphoid scapula in nearly every case exhibiting symptoms indicative of hypoplasia which I have examined. Delayed epiphyseal development as shown by the *x*-ray is practically a constant symptom.

That the secretions of the ductless glands are an important factor in physical and mental development has been amply proved by recent researches. How important perversions of these secretions are in the development of hypoplasia further investigation is necessary to prove. It is reasonable to suppose that defective development of the embryo resulting from an ovum vitiated to any extent and from any cause will, in the first few weeks of fetal life, when the ductless glands begin to appear, involve their structural elements. Unable to secrete to the extent to which they were destined, further defective development results on account of the intimate relationship existing between the process of growth and the pituitary, thymus, and thyroid glands. That retardation in mental and physical development may exist without the presence of hypertrophied tonsils and adenoids, and that hypertrophied tonsils and adenoids may fail to give rise to appreciable symptoms of retardation or deviation is not denied. I believe, however, that careful search will not fail to reveal some symptoms of hypoplasia, accompanied by signs of nervous instability, if not of actual defect, in those children in whom hypertrophied tonsils and adenoids are present.

Hypertrophied tonsils and adenoids as exciting causes of retardation. The alterations in the bony structures of the face and thorax secondary to enlarged tonsils and adenoids are too well known to require description, as is the malnutrition and lessened resistance to disease resulting from these conditions. I will, therefore, limit myself to the consideration of those conditions of retarded mental development caused directly by the mechanical obstruction resulting from their presence. Tonsils hypertrophied beyond the normal size or diseased and adenoids persisting beyond the normal period of atrophy are practically foreign bodies, and are peripheral sources of reflex irritation. The difficulty of breathing which children subject to these conditions experience further adds to their discomfort and gives rise to inability to concentrate the attention. Bonazzola[8] "found among four hundred school children at Bologna that one hundred and forty-one displayed a want of power to concentrate the attention. Examination of this group revealed adenoid growths in all but twenty-four. In the twenty-four with aprosexia without adenoid vegetations there invariably was nasal obstruction from some other cause, and the children were neurasthenic and presented signs of inherited physical degeneracy."

The aprosexia resulting from enlarged tonsils and adenoids is probably responsible for more cases of backward and deviate mental development than any other cause. Unable to apply himself to his studies, the child soon falls hopelessly behind his classmates and casts about for other means to keep his mind occupied, thereby getting himself into mischief of various kinds, and soon becomes a nuisance to his teacher and to his schoolmates. His school duties becoming hateful to him, he becomes truant with an enlarged field for his unrestrained activities, and finally coming into conflict with the authorities through his desire for constant change and excitement, ends in the Juvenile Court and the reformatory. Judge Mack's "straight road from adenoids to the penitentiary" is not an exaggeration. If he be of the phlegmatic type, content to plod without result, to stay where he is put, he becomes the dunce of the class, remaining in the same grade until, either outwearig the overstrained patience of the teacher or outgrowing his seat, he is advanced to the next grade, there to repeat the process. These are extreme cases, but they are to be found in every school, and many others lesser only in degree, in every class room. The hypoplastic child, fundamentally unstable, and still further handicapped by enlarged tonsils and adenoids with their attendant train of evils, is prone to respond to an exaggerated degree to faulty environmental influences of all kinds, and requires the most careful study and attention to ensure the advancement of which he is, in a great number of instances, capable.

Kyle states: "In at least 90 per cent. of cases of adenoid vegetation there is involvement of the Eustachian tube with deafness in varying degree." If the deafness be marked and occur before the child has learned to talk he will remain dumb. Even should he become deaf at the age of five or six, after he has acquired the faculty of speech, he will soon forget how to talk. There is no faculty upon which mental development is dependent to such an extent as upon that of speech. Thought in its higher functions exists only through expression by means of language, of which articulate speech is the most important manifestation. It is impossible for the child to reproduce what he has never heard, consequently two great stimulants to mental development are lacking, the power of understanding spoken language and the faculty of expression by means of speech. When to these handicaps are added the aprosexia and nervous instability usual in adenoid-bearing subjects it is small wonder that a diagnosis of idiocy or imbecility is often made. When the deafness is complete, after the removal of the primary cause, the treatment

should be the same as that accorded any other deaf and dumb child. When there is even a slight vestige of hearing remaining it is often possible by persistent and careful effort to not only develop speech but also to greatly improve the ability to hear.

Deafness in slighter degree may give rise to a peculiar form of speech practically identical in its symptomatology with idioglossia,[10] which condition is dependent upon a biological variation in the auditory word centers without general deafness. The analogous condition occurring as the result of deafness due to enlarged tonsils and adenoids may result either from slight deafness due to middle ear disease, which prevents the child from hearing all sounds except those of a certain pitch or intensity, which he will, of course, reproduce as he hears them, or to faulty subjective audition, the objective hearing being normal. In the latter case he hears words correctly and believes that he reproduces them as heard. His subjective auditory center has become accustomed to receiving faulty word impressions and has lost or failed to develop its power of differentiation. This is dependent upon faulty kinesthetic impressions derived from the peripheral musculature concerned in speech due to the presence of the enlarged tonsils and adenoids. For this reason, after tonsillectomy and adenectomy, a special course of training directed toward the development of the kinesthetic and auditory word centers is necessary.

Conclusions.—First, hypertrophied tonsils and adenoids occur in individuals who present symptoms of hypoplasia resulting either from hereditary or developmental causes. Second, there would seem to be an intimate relationship existing between perversions of the internal secretions of the ductless glands and hypoplasia resulting in hypertrophied tonsils and adenoids. Third, hypertrophied tonsils and adenoids are factors in retardation by their mechanical action as sources of reflex irritation and as impediments to the proper development of the cerebral centers concerned in speech. Fourth, removal of hypertrophied tonsils and adenoids is not sufficient, in cases of marked defect, to bring about restoration to normal. Special training and the institution of measures directed toward the amelioration of the underlying hypoplastic condition are necessary.

TYMPANO-MASTOIDITIS EXHIBITING MENTAL SYMPTOMS.*

By EMIL AMBERG, M.D.,

DETROIT, MICH.

On January 23, 1911, at noon, I was called to Grace Hospital to see Mrs. Ph. B., thirty years old. Briefly told, the patient had suffered from the grippe for ten or twelve days previous to that day. An otitis dated back a week, and caused the patient great trouble. The ear drum had been incised the day before. The temperature did not reveal much. The previous day it reached 99.2°. The patient was found lying in bed, giving one the impression of being very sick. The right eye showed the effects of a trauma foreign to the present trouble. The left appeared normal. The left outer ear canal was narrowed, swollen, and sagging. Some discharge was noticed in the depth. There was apparently great tenderness over the mastoid. I expressed the opinion that a mastoiditis was present which required immediate attention, but that the mastoiditis itself was not the only pathologic condition before us, because the somewhat delirious condition of the patient and the utter prostration were not agreeing with the usual picture of an acute uncomplicated mastoiditis. I operated immediately. The antrum was opened freely, but no free pus was encountered. The mastoid process was compact, and a few drops of pus were found after penetrating for about three-eighths to a quarter of an inch, according to my recollection. The findings in the operation did not coincide with the clinical picture, and yet the objective symptoms did not justify further interference just then. On the following day, on account of the apparent pain and the unusual utterances of the patient, I decided to investigate the dressing. Before I started I noticed that the patient's head was turned by the assistant or nurse rather more energetically and quickly than I am used to do it soon after a mastoid operation, and I expected an outcry, because patients are very prone to complain when the head is moved soon after a mastoid operation. To my surprise the patient did not mind the moving of the head at all. I was at once convinced that the expressions of pain and the excitement of the patient, which appeared to be alarming, were out of proportion to the physical pain, so far as I could establish it, otherwise the paradoxical occurrence could not be explained.

The history of the patient revealed that the patient had received an unusual amount of anodynes and hypnotics, which, however, did not alleviate her very much. I reasoned that, aside from a possible idiosyncracy against anodynes, even an organic mastoid complication should have been influenced to a greater extent by the same, and assumed that the nervous system was in a state of abnormal reaction. A drug habit was denied by the husband. I tried to persuade the patient to go to sleep by repeating very frequently the words "you go to sleep now," and succeeded in quieting her considerably, yet she declared that she had to have a hypodermic and to hold her husband's hand. I told her she would get a hypodermic, and instructed the nurse to give her a saline hypodermic. I called the husband aside and asked him how much nourishment his wife had had lately. He told me that she had had very little for about sixteen days. I

*Read before the Detroit Society of Psychiatry and Neurology, April 6, 1911.

then ordered a gradually forced nourishment, and replacement of the anodynes as much as possible by eggnogs with whisky. The improvement became shortly noticeable, and she progressed to recovery. The patient herself told me, March 28, 1911, in my office, that she did not recollect much of what had happened in the hospital; that she remembered that she was taken to the hospital and that they took off her things and gave her a hypodermic because she was in such agony. The ear did not discharge at that time, but she had pain behind the ear. She remembers that Dr. M. said that the ear had to be lanced, but that he could not do it, and she asked whether she would not be anesthetized in her room. For a few days she tried to turn her head, she remembers, but could not do it. Mr. B. turned it for her. She said she did not know me when I came in. One night patient says she saw her little nephew, who had been drowned about two years ago, sitting on her feet, and she told him to get off. She was trying to get out of bed, but could not. She asked the house doctor to lift her, and then does not remember anything more. She did not remember the physician who lanced her ear on January 22, so that she did not know him when he presented himself shortly before she left the hospital. The sister reported that the patient said, while in bed in the hospital, that a man came to her all dressed in white and laid a little doll in white in her arms, and that that was her casket, and they were calling her home. She said she was going home, and then going with her mamma (who is not living) and the other angels. She said that they were starving her. She complained to her sister about pain in the head, first in the back of the head and then on top of the head. The husband said that once or twice a day, sometimes oftener, especially toward the evening, the patient had spells during which she did not seem to recognize anybody. One night he was called to the hospital, where he found his wife unconscious, and was told she might not live till morning.

The patient asked to be taken home unreasonably soon. One day when convalescent she kept moving her legs in bed. I told her to stop it. She said that she could not help it, whereupon I told her energetically that she had to discontinue it, that she was not a three-year-old child, and that she could stop it if she wanted to. The patient became quiet and told me, "I do not like you." Some time later, when the patient was in my office and practically well, she moved her hands nervously in the same manner.

Remarks: The condition might have been aggravated by toxins and by the large amount of drugs. It is, however, more reasonable to assume that the inanition and exhaustion furnished the basis for part of the disturbance. The clinical appearance, the laboratory examination (urine and blood), and the findings at the operation, together with the subsequent course of the disease, do not give a simple clinical picture, and I do not think I am far out of the way when I assume that we had before us a patient of hysterical disposition, who suffered from an affection which bordered on a collapse delirium. The same condition might have occurred if any other organ had been affected. The differential diagnosis was of great importance on account of the close connection of the ear with the brain, which always creates the suspicion of a propagation of the disease from the primary focus. Furthermore, a complication on the part of the brain or its coverings does not often admit of much delay. This case demonstrates that a single apparently insignificant fact suggested a way of reasoning which made the conception of the condition more clear and influenced our therapeutic measures, with happy results.

A CASE OF EXTENSIVE HERPES.

By GEO. O. WILLIAMS, M.D.,

GREENE, N. Y.

The patient was a lady, aged 68. On March 8 the herpes appeared, simultaneously on the left upper lip, in the left naris, left inner canthus, in the left middle ear, and external auditory canal from the meatus back.

An enormous serosanious discharge accompanied the aural lesion, saturating cloth after cloth. The membrana tympani and the ossicles were carried away. Hearing was nil with the watch at contact. Illumination showed the pulsating arch of the auditory artery. Treatment consisted in a free application of a saturated solution of alum to the naris, the lip, and the inner canthus, and instillation of the same freely into the auditory canal, and subsequent packing the canal with boric acid. The external lesions were immediately subdued; the aural discharge became purulent. After a week the alum solution was dropped, and irrigation of the canal and subsequent boric acid packing continued. The purulent discharge gradually diminished.

On the twentieth day a narrow rim of new tissue was noticed at the seat of the destroyed membrane. The packing was dropped, and twice daily gentle irrigation was made with weak boric acid solution. The rim of new tissue increased and the lumen gradually diminished. The arterial pulsations remained visible until the complete closure of the opening. This occurred on the forty-second day. The purulent discharge ceased at the same time. Hearing by loud watch one and one-half inches. Duration of tone of *E* fork held between tragus and antiragus, within the concha, five seconds. Examination on the eightieth day—hearing by faint watch, three inches. Duration of tone of fork, fourteen seconds. The tone of this fork is audible by a normal ear thirty-five seconds. Should the fork come in contact with a stray hair the tone instantly stops.

The adventitious membrane has nearly the color of a normal drum, but is minus the outline of the ossicle. The case is of interest as illustrating nature's repair of a badly damaged ear.

Mammary Hypertrophy of Puberty.—Henri Caubet describes a disease of puberty that makes life miserable for some young girls. This is a hypertrophy of the mammary glands at the period of puberty to such an extent that the glands become a burden to the girl, hanging down to her abdomen or even to the knees, so that she cannot stand for the weight, or must remain in bed. The health of the girl fails, she becomes thin and weak, and menstruation is absent. The growth consists of an immense simple hypertrophy of the glandular structures and framework of the breasts. This hypertrophy comes on rapidly and becomes immense in the course of a few months. In some cases the mother was affected in the same way, so that heredity in some cases is an etiological factor. In general puberty seems to be the cause of the growth. The only treatment that is of any avail is the amputation of the breasts.—*Archives de Médecine des Enfants.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

New York, September 2, 1911.

CARBOHYDRATE TOLERANCE AND THE POSTERIOR LOBE OF THE HYPOPHYSIS CEREBRI.

THE discovery by Crowe, Cushing, and Homans of a reducing substance in the urine of animals upon whom a partial hypophysectomy had been performed stimulated further investigation along this line, the results of which are presented in a communication by Emil Goetsch, Harvey Cushing, and Conrad Jacobson in the *Bulletin of the Johns Hopkins Hospital,* June, 1911. Having noted that postoperative spontaneous glycosuria bore a definite relation to the surgical manipulations of the gland, and that the brief period of carbohydrate intolerance was followed by a reestablishment of tolerance at least to the normal, these observers determined to test these points more systematically.

As the result of their experimental and clinical studies they have shown that the secretory product of the posterior lobe of the hypophysis (*pars nervosa et intermedia*) is discharged into the cavity of the third ventricle, becomes dissolved in the cerebrospinal fluid, and enters the blood stream by way of the dural sinuses. Operative manipulation of the infundibulum and hypophyseal stalk produces a transient hyperglycemia due probably to the setting free of an excess of the stored-up secretion, which in turn causes the discharge of stored glycogen. For the succeeding few days carbohydrate tolerance is considerably diminished, "alimentary glycosuria" being produced by a smaller amount of sugar than was previously required. If the damage to the hypophysis is such as to create a permanent insufficiency of the posterior lobe secretion, the temporary lowering of the assimilation limit is succeeded by an abnormal and enduring augmentation in the tolerance for sugars. This tolerance can be promptly lowered by the coincident intravenous or subcutaneous injection of posterior lobe extract, which, furthermore, lowers the sugar tolerance of the normal animal, causing glycosuria when given in sufficient dosage. Accompanying this increased tolerance resulting from insufficiency of the posterior lobe or of its secretion, there is a tendency toward a generalized adiposity, suggesting a conversion of the stored sugars into fat. There is also a tendency toward a subnormal body temperature, which suggests an imperfect oxidizing or metabolizing capacity. Conversely, repeated injections of posterior lobe extract in the normal animal are apt to cause a profound degree of emaciation resulting presumably from excessive catabolism.

The clinical studies in this subject made by Goetsch, Cushing, and Jacobson present a number of important results. It is shown that intracranial lesions occasioning stasis of the cerebrospinal fluid, and therefore preventing the absorption of the secretion of the posterior lobe, will lead to symptoms of posterior lobe insufficiency. The most common source of moderate grades of this condition is an internal hydrocephalus. Another source is in tumors arising in the interpeduncular space and directly compressing and deforming the infundibulum attachment and "blocking" the secretion. A third source is a preexisting hypophyseal hyperplasia, just as myxedema may supervene on states of hyperthyroidism.

"It is well known," state these observers, "that hyperglycemia is of frequent occurrence in acromegaly and gigantism—clinical states which presumably represent, at the outset at least, a condition of hyperpituitarism, the pars anterior doubtless being chiefly responsible for the skeletal changes. We believe, however, that there is an inevitable tendency in these states toward an ultimate glandular insufficiency—toward dyspituitarism, in other words. Hence, in all probability a lowered sugar tolerance will be found only during the active stages of these maladies. Thus in all but two of the ten cases of acromegaly that we have studied the individuals have begun to show present evidences of posterior lobe hypoplasia which are recognizable through the laboratory experiences with animals suffering from comparable states which have been experimentally produced. They are acquiring adiposity, have subnormal temperatures, and often show an extraordinarily high carbohydrate assimilation limit. In view of this marked transition from a low to a high sugar tolerance which occurs during the progress of the malady, the discordant results of the past studies of metabolism in acromegaly are not surprising." It is suggested that the polyuria which is apt to be associated with these pituitary lesions may present a clinical picture readily mistaken for diabetes mellitus or diabetes insipidus. Possibly also the fleeting glycosurias following fractures of the base of the skull are induced by trauma of the posterior lobe or its infundibular attachment, similarly to those induced by operative manipulation of these structures.

In concluding the summary of their important investigations, which cannot fail to be of practical value from the clinical viewpoint, these observers say that "if loss or diminution of the internal secretion of the pancreas robs the tissues of their power of metabolizing carbohydrates, certainly loss or diminution of the secretion of the hypophyseal posterior lobe greatly enhances their power in this respect. In view of the generalized adiposity, not confined to the panniculus alone, but observable also in liver and muscle as well as in the other organs in these states, it would seem that functional deficiency of the posterior lobe permits the excess of stored carbohydrates to be transformed into fat. In

these states of beginning adiposity indicating a pituitary hypoplasia, glandular administration is indicated, and it is possible that the therapeutic dosage for the individual case may be determinable on the basis of the quantity of extract necessary to produce mellituria with an amount of ingested sugar which would be expected to represent the individual's normal assimilation limit."

AUDE SAPERE.

However inadequate the educational theory of Dr. Boris Sidis, he has unquestionably struck in his recent pamphlet one resounding major chord, and based on the fundamental, that is, his insistence that our common system of teaching greatly errs in not telling children something at least of the ills and the horrors of life, this omission weakening them and placing them at a disadvantage in maturer years. This is a theme that touches close the high-minded physician and every physician at all worthy the proud name of doctor—the learned man, the teacher of men. No phase of human wrong certainly is more conspicuous at our present day than that concerned with sexuality, and especially with its deeper relation to lasting happiness and to lifelong misery. Every thinking man and woman knows that as things are few adolescents ever become fully aware of the most basal fact in life—namely, the inherent unification between bodily love and that "affection that hopes and endures and is patient." This useful knowledge never comes perhaps until forced by irreparable harm, resulting very generally in a half-felt cynicism whose ultimate results are gonorrhea and syphilis, abortionism, and overcrowded divorce courts. Then it comes distorted, debased, perplexed and cynical.

Boys and girls do not need the sexual anthropology of Ploss and Bartels, of Forel, or even all that of Havelock Ellis; there is too little of the heights in all of these. They do need, however (who shall tell how much!) to have impressed upon them (in a way the prudish and conventionalized churches have long since failed to impress) that genuine love, life-long and heaven-high, is their best chance of *happiness* here and perhaps hereafter. The physician can tell them how voluntary and how autosuggestive such love can be. Our boys and girls need to *feel* what DeMorgan so beautifully expresses: "All was not Vanity, preach whoso might! So long as Love itself—the mystery of all mysteries—shall remain unsolved, there is an immeasurable music beyond the octave-stretch, forlorn of our fingers, an unfathomable ocean beyond our little world of pebbles on the shore." This mystery the adequate physician, if any one, can reveal—the transcending satisfaction that lies in the unity of that aspect of love that brings us our children with the aspect that means the life-long loyalty to a wife or husband. As Maurice Hewlett says of "Sanchia," "So her body's beauty is but a poem written by God about her soul," and as another poet writes it, "Love that hath no beginning hath no end."

The "ideal love" and the actual "lust," in short, seem too far apart to too many of our young men and women, and needlessly so, for they are parts of a whole, a rule of life, delights alike in one order of things, and the young people can be made by competent hearts to see them so. In the absence of some one strong voice whose clarion call, as in the Middle Age, can attract every mind to one needful and vital idea, it behooves the numerous physicians in this twentieth century to rise to their high privilege (*noblesse oblige!*) of dignifying that which in a more evolved age will surely dignify itself. If, as the great Augustine was wont to say, "Inter feces et urinam nascimur," yet as Ellis answers, "It may be said, in reverence, that the passage through the channel of birth is a sacrament of Nature more sacred and significant than man could ever invent." A later age will go a step further yet and the Creator at last be justified!

Of course, not many years from now, educational system, public and private, will teach as a routine, but easy task, this phase of the unity of body and soul, the mutual loyalty of man to woman, but until that happy day shall come it is to the physician that the world must look for the distillation of sexual wisdom among the young, the philosophy of life and love. From him it will come with a force and impressiveness derivable from no one else, making for a life-long, death-binding happiness, not less than for the most rapid uplift of our race.

PATHOLOGY OF SLEEP.

The nosological position of sleep disorders, especially of insomnia, still continues to perplex neurologists. While one will say that insomnia is a secondary consequence of nervousness, another insists that it is itself nervousness, *i.e.* by far the most common manifestation of the latter. From a third viewpoint insomnia of artificial or exogenous source tends to induce a nervous state and hence eventually a vicious circle. Mere restlessness or motor hyperactivity is known to be a condition greatly favoring insomnia, and in such cases the best hypnotic will be the drug or other resource which antagonizes this activity or which can remove its causes. Many a subject who gets depressing hypnotics and sedatives really requires only mild antispasmodics or a warm bath. Some individuals remain in a state of high wakefulness, yet are physically tranquil. In some of these cases at least the patient can hardly be said to require sleep, even if it be his bedtime. His mind is normally active and perhaps the best course to pursue would be to work or study until a natural demand for sleep came. Generally speaking, however, persistent wakefulness in one seeking slumber engenders restlessness, and as already stated the latter state is highly unfavorable for sleeping.

At a recent meeting of the Aerztlicher Verein of Hamburg (*Berliner klinische Wochenschrift*, June 26) Trömner attempted to assign a definite nosological status to sleep disorders. He defined sleep as a periodically supervening act for the autoregulation of the body. It is not synonymous with tiredness, but rather the reaction of a healthy organism to the condition of fatigue. Insomnia has been found to be present in over 60 per cent. of neurasthenics, and is two and a half times more frequent in women than in men. Certain cases of insomnia are clearly

due to exogenous causes, as heart disease, fever, pain, abdominal discomfort from flatus, etc. In some cases abuse of sleep in time militates against sleep, as in night workers. There is also a climatic insomnia. Primary insomnia comprises a number of syndromes. There is a pure insomnia, the so-called sleep neurosis, which may be the only evidence of a neurasthenic state. There is the insomnia of overfatigue which is a very familiar phenomenon and an evidence of neuropathy. A condition opposite to this is sleeplessness from underfatigue already alluded to; and in close relation to this is the so-called fear of insomnia which may amount to a true phobia. The insomnia of depression is an important type, for there is a notable association constantly present between sleeplessness and mental depression. Trömner terms this form agrypnia of involution. Periodical insomnia is also associated with periodic depression.

Of sleep disorders other than insomnia the author mentions somnolence as an affection in no wise affiliated with hysteria and epilepsy, but rather an imperative neurosis. Disturbed sleep is divided into sensory (vertigo, optic, and acoustic paresthesiæ), affective (nightmare, pavor nocturnus), and motor (somniloquism, somnambulism, and jactitation). Enuresis nocturna is not a pure neurosis, having a local component. Motor disturbances are best treated by suggestion, and all others, including insomnia, by the latter and dietetic and physical therapy in combination. We cannot, however, wholly dispense with drugs.

Acute Anterior Poliomyelitis.

Anticipating a return in epidemic form of acute anterior poliomyelitis, the New York State Department of Health devotes its July Monthly Bulletin very largely to a consideration of this disease and to the methods which have been inaugurated for its control. On July 31 a conference of about twenty-five medical officers of the State Department of Health was held at Albany to discuss the methods of field investigation to be used in the event of its reappearance. The general practitioner can greatly supplement the special investigation into treatment and etiology by collaboration with the Rockefeller Institute, which announces its desire to receive and treat gratis acute cases of anterior poliomyelitis during the present summer and fall. In the event of fatal cases where an autopsy is held it is desired that specimens of portions of the spinal cord, nasal mucosa, tonsils, and adenoids be preserved in glycerin and forwarded to the institute. It is especially important that these studies be carried out on a large basis and that sufficient data be collected to furnish the statisticians with material for arriving at logical conclusions. Indeed the responsibility of investigation and solution of the cause of any disease rests quite as much upon the shoulders of the general practitioner as those of the laboratory men; for without an adequate knowledge of the clinical features of disease, what are its avenues of infection, how one case leads to another, the seasonal, climatic, and individual factors which favor its spread, there is little hope of the bacteriologist alone being able to solve the problems involved. The epidemics of acute anterior poliomyelitis in New York State in 1907 and 1910 have been rather closely studied and as a result of the statistical compilations by Frost of the United States Public Health and Marine Hospital Service and the laboratory research work of Flexner of the Rockefeller Institute we have reasons for believing that the disease is caused by some ultramicroscopic organism, that it is probably transmitted by some insect as a carrier, that the portal of entry is the upper respiratory passages, and that the infectious agent can be carried by healthy persons or those who have had the disease as well as those who are ill. Furthermore, the recent aggregations of clinical data teach us that there are numerous atypical forms which may arise and for which we should be on the lookout, especially during the presence of an epidemic. Considered in the light of its high mortality and the far reaching economic effects resulting from the more or less complete paralysis of limbs in those cases which otherwise recover, thus leaving behind its trail of lifelong cripples, acute anterior poliomyelitis is especially worthy of the best efforts of the students of preventive medicine.

The Rôle of the Visiting Nurse.

The visiting nurse in the country, and especially in New York, might well say *veni, vidi, vici.* She has come and has come to stay. She has observed how matters stand, and if she has not conquered the diseases and complaints with which she is brought into contact she has at least played an important part in the fight against ill health and in preventive medicine, and she has conquered, or nearly so, the prejudice existing against her and her ministrations. To the *American Journal of Nursing* for August, 1911, C. E. A. Winslow, associate professor of biology, College of the City of New York, contributes an article with reference to the visiting nurse from a public health standpoint. The writer thinks that the visiting nurse is the most important figure in the modern movement for the protection of the public health. The visiting nurse is mainly concerned with school inspection, with tuberculosis, and with the reduction of infant mortality. Visiting nursing was inaugurated in Great Britain, but it has attained its highest stage of development in New York City. Miss Waters, in her book on "Visiting Nursing in the United States," published in 1909, mentioned twenty-four cities which at that time employed nurses for school inspection, and its present status is well summed up in the following paragraph, quoted from Gulick and Ayres' "Medical Inspection of Schools": "To sum up the case for the school nurse, she is the teacher of the parents, the pupils, the teachers, and the family in applied practical hygiene. Her work prevents loss of time on the part of the pupils and vastly reduces the number of exclusions for contagious diseases. She cures minor ailments in the school and furnishes efficient aid in emergencies; she gives practical demonstrations in the home of required treatments, often discovering there the source of the trouble, which if undiscovered would render useless the work of the medical inspector in the school. The school nurse is the most efficient link between the school and the home. Her work is immensely important in its direct results and very far-reaching in its indirect influences. Among foreign populations she is a very potent force for Americanization." Perhaps the most important of the duties of the visiting nurse is in the part she plays in the efforts to reduce infant mortality. In

this field her services are essential. The keynote of the situation as regards the fight against disease is to educate. The nurse is primarily and above all an educative factor. Disease will exist and flourish so long as ignorance prevails, but disease will wither and its prevalence abate in exact proportion to the increase of knowledge. The rôle of the nurse, being chiefly educative, is therefore one of the greatest forces for good in modern life. To Miss Wald is due the inception of visiting nursing in this country, and to the same woman is also owing its development on special lines.

News of the Week.

Measles in Samoa.—Advices from Tutuila, Samoa, say that there has been a deadly epidemic of measles on the islands of American Samoa, 219 deaths having been recorded up to July 23. The mortality due to the disease or directly attributable to it has been nearly 10 per cent. of the population of the towns from which returns have been received. This is the first serious epidemic of measles in these islands in nineteen years.

Cholera in Italy.—According to official figures of the cholera situation in Italy, published August 28, there have been 351 cases and 153 deaths in Sicily, 201 cases and 81 deaths in the city and province of Naples, 292 cases and 98 deaths in the province of Caserta, 25 cases and 14 deaths in Rome, 150 cases and 65 deaths in Leghorn city and province, 134 cases and 68 deaths in Genoa city and province and 534 cases and 180 deaths elsewhere. This is a total of 1,687 cases and 659 deaths. In Verbicaro, a town in the province of Calabria, the peasants have been incited to riot under the belief that the sanitary efforts of the physicians and nurses were intended to spread the disease. They set fire to the town hall, and killed the mayor and two Red Cross nurses. It is noted as a curious fact that the father of the murdered mayor was also mayor and was killed in a similar peasant outbreak fifty years ago.

Poliomyelitis in Boston.—Boston is reported to have 10 cases of poliomyelitis, North Adams 6, and Woburn, another suburb of Boston, 4. When Dr. Shepherd, the State Health Officer, was called to the latter place, he criticized the laxity of the local authorities and insisted on quarantining the cases as strictly as is done in scarlet fever.

Typhoid Epidemic in Orphanage.—Out of 113 cases of typhoid fever that have developed in the Bronx since July 21, 35 have occurred in the Roman Catholic Orphan Asylum. As a result of its investigations the Health Department states that the epidemic is probably due to flies and mosquitos and not to the milk or water supply. For the week ending August 26 there were 91 new cases reported for Manhattan and the Bronx, as against 135 for the preceding week. This leads the Health Department to express the opinion that the high point of the outbreak has been passed. The number of deaths for the week was 31, or 100 per cent. more than during the preceding week. These deaths, however, were from cases reported from one to three weeks ago.

Compulsory Vaccination in the Army.—Major General Leonard Wood issued an order on August 28 making it compulsory for every officer and enlisted man in the United States Army under forty-five years of age to subject himself to vaccination against typhoid fever. Heretofore it has been voluntary on the part of an officer or private in the army whether he should subject himself to this experiment. The War Department has become thoroughly convinced of the efficacy of typhoid inoculation and this order will go into effect immediately.

Glanders in Ulster County.—A report comes from Newburg, N. Y., that there is a serious outbreak of glanders among the horses employed in the work on the New York aqueduct and that 30 horses have been isolated for observation by the State Department of Agriculture.

Ambulance Accidents.—A street car collided with a Bellevue ambulance at Broadway and Twenty-sixth street on August 23 injuring Dr. Hoffman, the ambulance surgeon, and the driver, and badly damaging the ambulance. An ambulance belonging to the Williamsburg Hospital, Brooklyn, collided with a street car on Wyckoff avenue on August 16. The ambulance surgeon escaped injury, but the ambulance was completely wrecked.

Civil Service Examinations.—The United States Civil Service Commission announces an examination to secure eligibles for vacancies in the positions of bacteriologist and pathologist in the Bureau of Science, Manila, P. I. The salaries are $2,000 with opportunities for promotion. Applications must be properly executed and filed with the Civil Service Commission before September 23, 1911. Applicants may make application either to the United States Civil Service Commission, Washington, D. C., to the secretary of the board of examiners, post office, Boston, Mass.; Philadelphia, Pa.; Atlanta, Ga.; Chicago, Ill.; St. Paul, Minn.; Seattle, Wash.; San Francisco, Cal.; Custom House, New York, N. Y.; New Orleans, La.; Honolulu, Hawaii; Old Custom House, St. Louis, Mo.; or to the chairman of the Porto Rican Civil Service Commission, San Juan, P. R. An examination will be held on September 20, 1911, to secure eligibles to fill vacancies as they may occur in the position of trained nurses in the Isthmian Canal, Philippine, and Indian Services. Application blanks may be secured from the secretary of the United States Civil Service Commission at Washington, D. C., where information may be secured in regard to places of examinations.

Another Plan for the Reduction of Infant Mortality.—The Committee for the Reduction of Infant Mortality of the New York Milk Committee expresses itself as satisfied with the results obtained by the allied agencies in their warfare against diarrheal diseases this summer. It will now turn its attention to the prevention of infant deaths due to congenital troubles. These cause about 17 per cent. of all infant deaths. The committee is now giving special attention to 1,000 expectant mothers in an endeavor to bring to bear all of the community's resources which may enable the mothers to bring children into the world who shall be strong enough to combat the many foes that await them. An arrangement has been made with the Russell Sage Foundation by which a special nurse will be detailed to devote her time to this work. In addition to medical care and instruction in hygiene, help will be provided for the mother in case she is overworked. No midwives will be allowed to handle any of these cases. After confinement rest will be provided for the mothers and the children will be referred to milk stations. Last year about one-third of all infant deaths occurred among children not yet one month old; it will be the endeavor of the committee to prove by these 1,000 cases that this death rate can

be materially lowered. If this study proves that this is possible an active campaign will be undertaken along these lines next summer.

State Board Examinations.—There were 147 applicants who presented themselves before the Board of Registration of Massachusetts; of these 96 passed and 53 failed; that is 36 per cent. of the applicants failed. In the State of Oregon 96 applicants presented themselves before the State Medical Board, of whom 61 passed while 35 failed. At the recent examinations before the State Licensing Board of Alabama 86 applicants presented themselves and all passed and were given licenses to practise medicine.

Mrs. Harriman Endows Laboratory.—Dr. F. K. Ainsworth, chief surgeon of the Southern Pacific Railroad system, announces that Mrs. E. H. Harriman has given $50,000 for the establishment of a bacteriological and pathological laboratory in San Francisco for the benefit of the employees of the company.

Red Cross Seals.—If expectations for the sale of Red Cross Christmas Seals this year, as announced by the National Association for the Study and Prevention of Tuberculosis to-day, are realized, one hundred million of the holiday stickers, or a million dollars' worth, will be sold. Postmaster-General Hitchcock has approved of the design of the seal. Owing to the fact that many people last year used Red Cross Seals for postage, the Post Office Department has given orders that letters or packages bearing seals on the face will not be carried through the mails. This will be the third year that the seals have been sold on a national basis. In 1908 over $135,000 was realized from the sale; in 1909, nearly $225,000; and in 1910 nearly $310,000.

The Medical Section of the American Life Convention is to hold its annual meeting at the Hotel Schenley at Pittsburgh on September 20, the day before the opening of the convention. At this meeting some papers of great interest to medical directors and life insurance examiners will be read, and all medical directors, examiners, actuaries, or officers of companies who are interested are cordially invited to attend and to participate in the discussion of the papers. The following is the program of papers to be read at the meeting: (1) "The Transmission of Tuberculosis During Fetal Life," Dr. Harold A. Miller, Medical Director Pittsburgh Life & Trust Company; discussion opened by Dr. Victor C. Vaughan, Jr., Associated Medical Director Michigan State Life Insurance Co. (2) "The Healed Tuberculous Lesion from a Life Insurance Standpoint," Dr. George W. Parker, Medical Director the Peoria Life Insurance Company. (3) "Blood-Pressure," Dr. Henry Wireman Cook, Medical Director Northwestern National Life Insurance Company. (4) "Nervous Diseases as Applied to Life Insurance," Dr. John S. Turner, Medical Director Southland Life Insurance Co.; discussion opened by Dr. J. H. Florence, Medical Director Great Southern Life Insurance Company, Houston, Texas. The secretary of the section is Dr. F. L. B. Jenney, Marquette Building, Chicago.

Consolidation of Medical Colleges.—Announcement is made that the College of Physicians and Surgeons of Memphis and the Medical Departments of the University of Nashville and of the University of Tennessee have united to form one medical school in affiliation with the University of Tennessee. The school will be located in Memphis and will be liberally equipped with the contributions of the three colleges. The registrar of the newly consolidated institutions is Dr. E. F. Turner, 879 Madison avenue, Memphis, Tenn.

Medical College Will Reopen.—The University Medical College of Kansas City, which closed its doors last spring, announces that it will reopen this fall and will be run henceforth as a clinical school of medicine and surgery. The requirements for admission have been raised so that they include a degree from a reputable college and two years in a medical school. Arrangements are being made whereby this institution may cooperate with universities and colleges in nearby States. The hospital in connection with the college will be improved.

The new addition to the Margaret Fahnestock Training School of the New York Post-Graduate Medical School and Hospital is completed and provides accommodation for 139 nurses. The former building accommodated sixty-seven, and was inadequate for the needs of the medical school and hospital building, now nearing completion.

Radium Institute Opened.—A radium institute has recently been opened in London. This has been made possible through the generosity of Viscount Iveagh and Sir Ernest Cassel. It is reported that the institute is the possessor of 15 grains of radium and will be able to treat thirty patients at one time.

Medical Building Burns.—The west side of the old medical building on the campus of the University of Michigan was destroyed by fire on the night of August 12.

Addition to Hospital.—Work has been begun on a four-story addition to St. Joseph's Hospital, Denver, Col. The new building will be constructed on strictly scientific lines and will contain forty-four rooms and eight suites of rooms. The estimated cost of the building is $100,000.

State Home for Mental Defectives.—Colorado is solving the problem of what to do with mental defectives who should not be placed in an insane asylum and do not fit in any other institution by erecting a large state institution which will provide a proper environment for this class of unfortunates.

A Hospital for Divers.—A report comes from London that a portable hospital has been devised for divers. This "hospital" is just large enough for the patient and a physician and is so constructed that the atmospheric pressure can be adjusted to the needs of the patient. It is said that there are only two of these decompression hospitals in existence, one being the property of the English Admiralty and the other belonging to the Russian Government.

A Detention Hospital for Topeka.—The City and County of Topeka, Kan., have begun the erection of a detention hospital which will provide room for forty beds and private quarters for those willing to pay for them.

New Children's Hospital.—Contracts have been awarded for the construction of a children's hospital for contagious diseases for Kansas City, Mo. Work will be begun at once and it is hoped that the building will be ready for occupancy by spring.

Annual School for Health Officers.—The annual school of instruction for health officers of the State of Vermont convened on August 21 in Burlington, Vt., and remained in session four days.

Department Store Helps Fight Infection.—As a part of the movement to abolish the public drinking cup in New York City, a department store announces that it will make a free distribution of several hundred thousand pocket drinking cups to school children. The reason for discriminating in

favor of children is because children suffer far more than adults from the evils of the common drinking cup.

Stray Animals in New York City.—The Society for the Prevention of Cruelty to Animals has been employed since June 1 in collecting stray dogs and homeless cats. During this period 113,186 cats and dogs have been captured; the record for a single night has been as many as 886 cats. This work has been undertaken not only as one of mercy in behalf of the animals, but as a protection to health, it being generally acknowledged that the stray cat may be a potent disseminator of disease.

Dr. C. O. Probst, of Columbus, Ohio, secretary of the State Board of Health, resigned his office on August 24.

Dr. John W. Russell has been appointed first assistant at the Matteawan State Hospital to take the place of Dr. Amos T. Baker, who recently resigned.

The Medical Society of the Missouri Valley, of which Dr. Donald Macrae of Council Bluffs is president and Dr. Charles Wood Fassett of St. Joseph secretary, will hold its twenty-fourth annual meeting at Omaha, Neb., on September 7 and 8.

The Late Dr. Matheson.—At a recent meeting of the Norwegian Hospital Alumni Association the following minute was adopted: "It is with feelings of sorrow that the Norwegian Hospital Alumni Association is called upon to record the death of Dr. Sewell Matheson, who died at his home on July 9, 1911, in the forty-second year of his age. In his death the association is deprived of one of its most esteemed and respected members. As one of the founders of the association he had always taken a most active share in its success, contributing much to its interest by the value of his experience and the amiability of his disposition and comradeship. He was a valuable asset to the association, to the medical profession, to science and art, and to the community in general. His professional career was marked by unusual devotion, fidelity, charity, loyalty, and enthusiasm. His personal character was distinguished by a high sense of integrity and ideals; he possessed a general personality which endeared him to all his coworkers, each of whom feels in his death a sense of personal loss."

Obituary Notes.—Dr. Henry Kay Kerr of Watertown, N. Y., a graduate of the Toronto School of Medicine in 1881, a member of the American Medical Association and the Watertown Medical Society, died suddenly of heart disease, August 22, aged 52.

Dr. Theophilus Steele of New York City, a graduate of Lexington Medical College, Ky., in 1852, died suddenly, August 24, aged 77.

Dr. George S. Foster of Putney, Vt., a graduate of the University of Vermont Medical College, Burlington, in 1874, died August 18, aged 63.

Dr. Joseph Nisbet LeConte of Atlanta, Ga., a graduate of Bellevue Hospital Medical College in 1898, died at his home August 13, aged 38.

Dr. J. H. Lester of Crudup, Ala., a graduate of the University of Pennsylvania, Department of Medicine, in 1878, died at his home August 14.

Dr. James Sullivan of Manchester, N. H., a graduate of Yale Medical School in 1875, died in Boston August 16, aged 58.

Dr. James M. Whittaker of Milledgeville, Ga., a graduate of University of Georgia, Medical Department, Augusta, in 1870, died August 12, aged 65.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DENTAL CONFERENCES, INTERNATIONAL AND BRITISH—ORAL SEPSIS—MOUTH BREATHING, CARIES, ETC.—SANITARY INSTITUTE—OBITUARY.

London, August 11, 1911.

The dental branch of the profession has been much in evidence and its conferences have been of interest beyond the specialty. First came the International Dental Federation's meeting, which was held this year at the Royal College of Surgeons and was cordially welcomed by the British Dental Association. In fact, the two organizations might, for the time being, have been regarded as united. Mr. W. P. Paterson, F. R. C. S., was president of both. The federation members were the guests of the association, as were a number of foreign visitors, both as to the social functions and scientific proceedings.

The president delivered an inaugural address in which he criticised the action of the State in regard to the protection of the public from unqualified persons and the inefficiency of the managements for the army and navy. Further, he maintained that the whole world would have to adopt school clinics.

Sir H. T. Butlin addressed the meeting at the college on the conditions of the mouth that were likely to be mistaken for cancer. The diagnosis he admitted was often difficult and he gave some striking illustrations. The state of the teeth bore an important relation to the health of the nation. He hoped to see the day when every dental practitioner would be a qualified physician or surgeon.

At the association's meetings there were a number of special papers. One was by Dr. Bardswell, superintendent of King Edward's Sanatorium, who said a good digestion was the best asset a consumptive could possess and the mouth was the first line of defence. At all dispensaries and sanatoriums skilled dental treatment should be a matter of routine. Not only so, but such treatment should be available for all classes, though he was afraid the time was not ripe for asking the State to provide it.

Mr. F. Harrison had a paper on the ill-effects produced by faulty breathing and excessive sucking of teats and "comforters" by infants. He would destroy all such things and institute nose drill three times a day. As early as eight years of age children in civilized countries suffered from decayed teeth.

Mr. Rushton followed up this subject with a paper on the "effects of mouth breathing on the facial contour." He declared dental irregularities increased of late and were accompanied by changes in the jaws, so that we were becoming an ugly nation, the round face giving place to the long, thin one and the mandible being protruded instead of retracted.

Dr. Cryen showed the value of *x*-rays. Dr. Cunningham described the Cambridge Dental Institute for Children. Mr. Wallis looked for benefit to the public health from school clinics, and Dr. Bogue presented a paper on the "Prevention of Dental Deformities." Closely related to these discussions were others at the recent Birmingham meeting, where oral sepsis and dental caries bulked largely in more than one section.

In the odontological, Mr. Erskine Young of Liverpool, said oral sepsis struck at the root of

national health. He attributed to this cause cases of anemia (septic), appendicitis, tuberculosis, and other diseases. Microbes gained admission through carious teeth and exposed pulps. Sir V. Horsley declared 750,000 London children needed dental treatment and school clinics only could deal with them effectually. Mr. Wallis said the County Council needed conversion and education. He advocated public lectures. Mr. Brooks spoke of the financial difficulty which would only be met by State Dentistry, the scheme of the Insurance Bill being extended to the dental branch.

Mr. Herbert Smale, of London, had a joint paper with Dr. Carmalt Jones on the "Bacteriology of the Tooth Brush," which might well give thought to many. Once used the brush was septic and every bristle might be looked at as an inoculation needle, ready to be the cause of anemia, gastritis and any microbic disease. To render the brush aseptic it would have to be boiled for 5 minutes after using. A new brush could be had for a penny and so a new one every day was available. They recommend trikresol, 1 per cent., for rinsing the brush, and when not in use that it should stand in formalin solution, 10 per cent. The mouth was a septic cavity, but that was no reason for driving the microorganisms into the tissues. There was considerable discussion on this subject, and Mr. Hopewell-Smith said india-rubber brushes could be thoroughly cleansed under a stream of water, and mechanical cleansing of the mouth was quite sufficient in ordinary circumstances. Antiseptics in the mouth were only needed in diseased conditions. This was the opinion of other speakers. It was generally agreed that the weak antiseptics found in various washes for the mouth had no effect on pathogenic organisms.

Dr. Sim Wallace took up the bread question, of which so much has been made, and said that bread did no harm except by lodging in crevices where it could ferment.

Mr. Hopewell-Smith spoke of the "abuse of sweets," and said their ill-effects were known to every practitioner. Some, as hand-bake, actually cracked the enamel. Others were colored with harmful dyes, and so on. Chocolate and coffee were specially bacteriophile. Professor Bostock Hill thought they would have hard work to persuade the rising generation that sweets were injurious. As a public analyst he found it very rare for dangerous dyes, etc., to be used.

Dr. Woods Hutchinson, a New York visitor, interposed by saying it was getting dangerous to be alive. He was not himself afraid of bread and he was strongly in favor of sweets, or as they called them in America, candies, for they helped to build up the bodies of young people. His views have been mentioned in the newspapers to the delight of the youngsters in many a household and the confusion of not a few doctors who have been forbidding such luxuries.

In connection with the Sanitary Institute's Congress a women's meeting on hygiene was held at which Dr. Eric Pritchard proposed the state endowment of motherhood, which if well organized, he held would eliminate many causes of death, due to poverty. He had been a strong believer in the sanctity of the home until his work with school children brought him into contact with thousands of mothers who had no conception of discipline, order, or obedience. Muddle, dirt and stupidity ruled in many such homes. The insurance bill did not safeguard the babies. Endowment should provide every lying-in woman with a capable midwife and health visitors, who could dispense free food, clothing and other necessities. In the discussion some thought it was proper to limit the number of children to reduce the great mortality of infants. Others held this would be against the welfare of the state.

In regard to other conditions of infantile mortality and disease several speakers strongly urged compulsory notification of disease, and one made out a rather good case from his point of view, for placing among the diseases to be compulsorily notified, ptomaine and food poisoning.

Dr. Samuel J. Gee, consulting physician to St. Bartholomew's Hospital, has died suddenly at Keswick, at the age of 71. He was honorary physician to the Prince of Wales (now King George). He was a distinguished student of University College, taking the M. D. and the University medical scholarship in 1865. He became Fellow of the Royal College of Physicians in 1870, and served as censor in 1893-97. He was a frequent contributor to medical literature. His "Auscultation and Percussion" reached a fifth edition in 1906. His "Medical Lectures and Aphorisms" went to a second edition in 1907. He delivered the Gulstonian Lectures in 1871 and the Lumleian in 1899. He wrote many articles in Allbutt's "System," Reynold's "System," and Quain's "Dictionary of Medicine."

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

BURNS OF THE CRANIUM AFTER ELECTROCUTION—FOREIGN BODIES IN THE URETHRA—LUMBAR RACHINOVOCAINIZATION—GENERAL ANESTHESIA WITH REDUCED CIRCULATION OR EXCLUSION OF THE FOUR LIMBS IN GENERAL ANESTHESIA—DR. CHARLES NÉLATON.

PARIS, July 30, 1911.

At a recent meeting of the Société de Chirurgie Quénu reported several observations of Guinard (of Saint-Etienne) on burns of the skull after electrocution. Accidents of electrocution occur generally as a result of touching cables which serve to carry motor force. These cables carry often 35 to 40 ampères under 10,000 volts. The electrocution which results from touching such a cable produces burns with black eschars, true carbonizations which often necessitate amputations. Guinard has seen cranial eschars of considerable size which would not permit a complete resection of all the burned bone. Here he has trephined as early as possible in the center of the eschar in order to guard his patient against encephalic accidents. Rochard has also observed burns of the skull in a woman who fell into a fire and had one half of the head completely burned. Rochard did multiple trephining and could obtain cicatrization only by means of grafts. Cure was obtained after some months, but some parts of the brain were protected only by osseous crusts. Routier observed a patient of 42 years of age in whom very severe symptoms resulted from the presence of foreign bodies which had existed for five years in the urethra. The patient had an elevation of temperature, a dry tongue, and a vast phlegmon of the entire scrotal region and the half of the abdomen below the umbilicus, with a fistulous orifice at the penoscrotal angle from which issued pus and infectious gas. The exploration of the urethra allowed of feeling 6 cm. from the orifice a stony scrotching which resulted from the presence of three large hairpins, which were ex-

tracted with forceps. Five years before, in a leisure day, the patient, a gardener, introduced the three hairpins into the urethra successively without being able to withdraw them. He suffered for some days and then ceased to feel them. He continued his work without interruption. A short time afterward abscesses formed and produced fistulæ, but it is curious to consider that this man was able to carry three long hairpins in his urethra for four years without being severely incommoded.

Forgue of Montpellier defended lumbar rachinovocainization before the Academy of Medicine. This method of anesthesia has not found among the majority of surgeons of France the success and appreciation that it deserves. It seems that the introduction of a new agent of slight toxicity, novocaine, should give in rachianesthesia as good results as in local anesthesia. From the point of view of technique, Forgue uses the sterilized solution of novocaine "Creil," 4 per cent.; the injection is made in the lumbar region and the dose varies from 5 to 10 centigrams, according to the age of the subject. Forgue has done 320 operations with lumbar anesthesia using novocaine; he obtained 306 good anesthesias in the 320 cases, a proportion of 95.5 per cent. Anesthesia begins generally five minutes after the injection; it invades the anoperineal region, the lower limbs, and progressively reaches the pelvis and even the thorax; after ten minutes it is complete. The average duration is 40 to 50 minutes. In the course of the operation there are no accidents; the pulse is generally slow, from 50 to 60 per minute; there is sometimes a paralysis of the sphincter which allows feces to pass from the bowels during the operation, but this little incident is rare and unimportant. The accompanying phenomena are unimportant; the operative shock is almost nil; secondary vomiting is absolutely exceptional, so that the patient can be fed normally very soon. No immediate or secondary bad result has been seen. Thus we see that rachinovocainization in the lumbar region has produced an excellent result and presents an almost absolute harmlessness which makes it preferable to general anesthesia. Pinard reported a case in which rachianesthesia gave an excellent result in a woman who was able to be delivered by cesarean section and have a living child extracted, thanks to this method of anesthesia.

Delagenière brought forward a method of anesthesia with reduced circulation by exclusion of the limbs in general anesthesia. This method, invented by Klapp in 1907, consists in using a narcosis in which the circulation has been artificially reduced in extent. Struck with the ease with which we can anesthetize subjects who have had a considerable loss of blood, Klapp had the idea of causing constriction of the limbs by means of elastic bands placed at the root of the limb, so as to exclude from the circulation the mass of blood contained in the members. One notes that the quantity of anesthetic needed to put to sleep a patient is proportional to the quantity of blood and the weight of the subject. Delagenière has collected 1,144 observations of general anesthesia with reduced circulation. The technique consists in applying a band of rubber at the root of each limb sufficiently tight to cause venous stasis. After a few minutes, when the limb is turgescent, we apply a ligature like an Esmarch band, or a simple rubber band drawn progressively tighter, so as to arrest at the same time the venous and arterial circulation. As soon as the bands are applied the respiration becomes more rapid and the movements of respiration become less deep. This phenomenon is due to the lessening and slowing of the circulation, which causes a diminished hematosis. The advantages of this method are a more rapid anesthesia, which comes on in two or three minutes; the sleep is deeper, the dose of chloroform needed is less, the awakening is more rapid, the accompanying organic troubles are less, vomiting is seldom abundant and disappears during the first day. Hepatics avoid icterus by retention and eliminate better the chloroform which they have taken. The inconveniences of the method are of slight importance; they are formication in the excluded members for some hours, and small ecchymoses of the skin, sometimes a slight weakness, or paralysis.. Perhaps the method exposes the patient more than the ordinary one to phlebitis of the limbs.

Nélaton, surgeon of the hospitals, member of the Surgical Society, died suddenly in the fullness of his powers and talent at hardly 60 years of age. He bore one of the greatest names in French surgery, for his father was one of the greatest French surgeons, and had a brilliant reputation. Charles Nélaton was excessively modest because of bearing the name of his illustrious ancestor. He was a conscientious surgeon and was especially interested in affections of the bones and articulations and in autoplastic surgery. In the Surgical Society his authority was great for he was well known as never advancing an idea until he was certain. Charles Nélaton died before his time surrounded by the unanimous affection and regrets of all who had known him.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

BISMUTH PASTE—PARALYSIS IN CIRRHOSIS OF THE LIVER—TREATMENT FOLLOWING OPERATION IN CARCINOMA—DISEASE OF THE CHROMAFFIN SYSTEM ASSOCIATED WITH EXOPHTHALMIC GOITER.

VIENNA, August 15, 1911.

THE treatment of cold abscesses by means of bismuth paste was the subject of a discourse before the Practitioners' Society by Emil Beck of Chicago. He described the rationale and technique of his method in the diagnosis and treatment of fistulous tracts and cold abscesses, referring particularly to the good results that he had obtained in cases of spondylitis and coxitis.

A lively discussion followed the reading of Dr. Beck's paper. Dr. Schmidt stated that he had employed this method with success in fifty cases in Eiselsberg's clinic. Dr. Stiasny reported that he had obtained favorable but transitory results in the treatment of anal fistula. Dr. Lotheisen had obtained the best results in the treatment of tuberculous spondylitis. For necrotic cavities he used, instead of iodoform emulsion, a novoiodine paste which gives a good *x*-ray shadow and which is nontoxic. Professor von Eiselsberg remarked that twenty years ago a French surgeon had recommended the injection of paraffine into cold abscesses. One disadvantage of this method was the fact that the paraffine would persist in the tissues, from which it could not be removed. Beck's method was valuable not only for diagnosis but also for treatment.

Paralysis of the extremities resulting from a neuritis occuring in the course of cirrhosis of the liver was observed in a male 34 years old by Hans Eppinger in van Noorden's clinic. The patient had

worked ever since his fourteenth year with lead dies, but had never given any manifestations of lead poisoning until three months before his admission, at which time his illness began with colic, vomiting after eating, and emaciation. Physical examination revealed marked anemia, the lead line on the gums, and urobilinuria. The pulse varied around 100, the blood-pressure was not increased, the second aortic sound was not accentuated, and at one time a slight glycosuria was noted. For a long time the patient had experienced a feeling of weakness and trembling in his hands and feet. After a short stay in the hospital the symptoms improved, but twenty days previously on awakening in the morning he could not move his arms and could barely walk. Many muscle groups of the arms and abdomen were paralyzed and some were atrophic with loss of both galvanic and faradic irritability. For a long time the patient had had dyspnea; the diaphragm responded but slightly to stimulation of the phrenics. The abdominal and cremasteric reflexes were absent but the patellar reflex was exaggerated. The presence of urobilin in the urine was evidence of a cirrhotic condition of the liver. Eppinger had observed in van Noorden's clinic the occurrence of sudden paralysis of neuritic origin in several cases of cirrhosis of the liver, and he regarded the above case as one belonging to this group.

Energetic treatment following operation in cases of carcinoma is recommended by Professor Hochenegg. For a long time he has been convinced that operation fulfilled only one indication: it removed the new growth but not the predisposition thereto, which predisposition consists in some unknown alteration in the organism and of its metabolism. Since this condition continues after the operation, recurrences are common; these have been regarded as relapses, but, according to certain observations made by the author, the so-called relapses are really independent of the first manifestations and are new expressions of the underlying causes. Hitherto he has had no means of confirming this hypothesis, but the discovery of the carcinoma reaction of Freund enabled him to demonstrate the presence of the cancer predisposition. The application of this test to cases before and repeatedly after operation by Arzt showed the presence, the continuance, and the disappearance of the cancerous predisposition. Hochenegg recommends that, if the reaction is positive, energetic solar and other light cures should be administered, for these have been effective in changing the positive into a negative reaction.

Disease of the chromaffin system associated with exophthalmic goiter was observed in a female patient by N. Lindenfeld. Four months previously the patient had noticed that her skin took on a brown coloration, which later disappeared but returned after a lapse of seven or eight weeks. These pigmentary changes were noted as follows: Large, dark areas appear on certain portions of the body and afterward fade; soon appear at many different parts of the body pigmentary spots as if caused by a spray of ink, which, however, like the larger blotches, are only transitory. There was marked tenderness in both renal regions, particularly on the left side, while there was none apparently in the epigastric region. Below one kidney an indistinctly defined resistance was felt. The blood-pressure varied but was not low and the patient lost in weight. This case was probably not one of pigmentary Graves' disease, that is, one associated with hyperfunction of the adrenal system, but was a combination of disease of the thyroid and that of the adrenal apparatus.

Progress of Medical Science

Boston Medical and Surgical Journal.

August 17, 1911.

A Report of Sixty Cases of Syphilis Treated with Salvarsan. J. H. Cunningham, Jr.
Boston's Hospital School for Tuberculous Children. E. A. Locke and T. J. Murphy.
Skin Grafting in the Repair of Contractures Due to Burns. B. Vincent, R. M. Green, J. F. Tomkies, and W. T. Graham.
Tree Cancer. A Striking Analogy Between Certain Vegetable Tumors and Malignant Animal Tumors. H. Packard.
An Unusual Monstrosity. G. R. Torbert.

Salvarsan.—J. H. Cunningham, Jr., reports satisfactory results in the treatment of sixty cases of syphilis with this drug.

Hospital School for Tuberculous Children.—E. A. Locke and T. J. Murphy describe the work of the open-air school and hospital established for tuberculous children in Boston, and controlled jointly by the Boston Consumptives' Hospital and the Boston School Department. The general results of treatment have, on the whole, been extraordinarily satisfactory. After admission the children show, almost without exception, an immediate improvement in their physical condition in response to the life in the open air, rest, and feeding, and the teachers have frequently noted a striking development in the mental powers also. As a rule the children enter into the routine of the school with enthusiasm, and the authors have never observed any hardship from the life in the open air, even during the most severe winter weather. On several occasions, when discharged, the child begged to be allowed to remain.

Skin Grafting in Repair of Contractures Due to Burns.—B. Vincent, R. M. Green, J. F. Tomkies, and W. T. Graham report four cases, showing the favorable result of skin grafting for cicatricial contractures due to burns, and suggest that this is a valuable method, with wide possibilities of application.

Tree Cancer.—H. Packard refers to the striking analogy between vegetable and animal tumors, particularly exemplified in the tumor growths on the red oak trees of Cape Cod. These show a localized primary infection, enormous multiplication of the host cells, metastasis to neighboring parts, and death of the host.

An Unusual Monstrosity.—J. R. Torbert describes a specimen of monster belonging to the type of uniovular twins, which are always of the same sex, and which communicate with each other by means of the vessels of the umbilical cords, near to or in the single placenta. One of them is usually fairly normal in structure, while the other shows an amount of deformity which is always considerable and may be extreme.

Modern Vitalism. C. E. Woodruff.
National Insurance Against Sickness and Invalidity. G. P. Forrester.
The Regressive Psychosis of Alcoholism. A. D. Bush.
Arteriosclerosis; Points in Its Treatment. B. Robinson.
Remarks on the Pathology and Surgery of Renal Infections. A Report of Three Cases. I. Collica.
Secondary Tumors of the Heart. H. LeB. Peters and L. S. Milne.
A Strange Case of Anaphylaxis. B. Kaufman.

Modern Vitalism.—C. E. Woodruff states that chemistry reduces vitality to very simple terms, the unstable combination of enormous numbers of molecules of three very stable atmospheric gases (N, CO_2, H_2O). Modern vitalism merely states that if protoplasm is alive so are the nitrogen compounds composing it, and so was the most primitive form of nitrogen compound, which was the ancestor of the modern compounds. The chemistry of the evolution of this primitive one, therefore, prepares on

for the final starting plunge taken by a few modern thinkers. The change from nitrogen to the living nitrogen compound was very gradual and extended over millions of years, so gradual indeed that no one can say when the function could be called vital. Therefore it is boldly asserted by these men that if the end products were alive so were the beginnings—so was the nitrogen itself.

National Insurance. By G. P. Forrester. (See page 491.)

Alcoholism.—A. D. Bush notes the power of alcohol as a subtle poison, acting upon the cells of the nervous system in the inverse order of their evolution.

Treatment of Arteriosclerosis.—B. Robinson states that the larger his experience and the more he watches cases of pronounced arteriosclerosis, especially in men and women past middle lift, the less frequently does he prescribe either digitalis or the iodides. If a cardiac tonic or stimulant is required, strophanthus, caffeine, and nux vomica are preferable by far and are not liable, in small or moderate doses, to do positive injury. They require also judicious watching and suppression at times, but not to the same degree as digitalis. To lessen supertension, where it is clearly indicated by reason of headache, fainting attacks, pallor, and general nervous irritability, sweet spirits of nitre in small or moderate doses, added to water, is the least injurious and most useful drug the author knows of, not excepting nitroglycerin and the nitrites. Supertension in arteries, like the physical changes upon which it depends and with which it is allied, is highly conservative and should not be combated by any unwise attempts to control or modify it. Important measures in the treatment are change of scene and occupation; fresh air; good diet, with limitation in the amount eaten daily, and avoidance of excess of meat, sweets, alcohol, sauces, fats, uncooked fruits, or vegetables; and abundance of water internally. Physical exertion should be moderate, the skin should be kept in good condition, and mild saline laxatives should be administered twice a week.

Renal Infections.—I. Collica reports three cases of surgical kidney and discusses the pathology and surgery of renal infections.

Secondary Tumors of the Heart.—H. Le B. Peters and L. S. Milne report three cases of secondary malignant tumor of the heart, two of carcinoma and one of lymphosarcoma. They state that tumor metastases in the heart occur as a result either of direct extension by the lymphatics from neighboring structures or via the blood stream either by direct implantation upon the endocardium or by embolism of the coronaries. The symptoms of tumor of the heart are exceedingly varied, no pathognomonic sign being recognized. Palpitation, precordial pain, cardiac distress, dyspnea, arrhythmia, cyanosis, and other signs of loss of compensation are sometimes noted.

Anaphylaxis.—B. Kaufman reports the occurrence in himself of extraordinary swelling of one arm, which was also the seat of intense pain and itching, following an injection of 1,000 units of diphtheria antitoxin. There were also nausea and general urticaria. The author had seven months previously been injected with 500 units of antitoxin.

Anatomical Conditions Bearing on the Relations Between Diseases of the Eye and Diseases of the Accessory Sinuses. W. E. Sauer.
Eye Complications Arising from Diseases of the Nasal Accessory Sinuses. A. H. Andrews.
Operative Treatment of Suppurative Sinus Disease Producing Orbital Complications. J. H. Bryan.
Gangrene of Finger Caused by 5 per Cent. Phenol Ointment. O. F. Schussler and M. A. Stern.

Fundamental Principles of Pediatrics—By H. D. Chapin. See MEDICAL RECORD, July 29, 1911, page 249.

Mechanical Devices for Closing Wounds.—E. W. Andrews states that he has constructed several forms of forceps by means of which one can sew the skin and deep layers more smoothly and rapidly than by hand. He also describes new forms and new applications of metal clips. The advantages noted for these are speed of application, asepsis, rapid healing, absence of pain, absence of scars, a ridge-shaped or folded up suture line, and no perforation of the skin. The only disadvantages are lack of strength and want of flexibility, causing pressure, irritation, or ulceration. The author recommends the use of clips in intestinal work. As a substitute for artery forceps and ligatures, the small clips are of great value. The metal used for outside work is German silver. To secure absorption of the little metal staples after these are placed deep in wounds, the author has tried aluminum, zinc, and magnesium. The last is ideal in being quickly absorbed, but is so brittle that it breaks easily. An alloy of these metals is now being used, and promises well for rapid absorption.

Gonorrheal Osteoperiostitis of the Long Bones.—By S. H. Watts. See MEDICAL RECORD, July 8, 1911, page 100.

Aims in Medicine.—C. F. Stokes states that the two kinds of conscience as distinguished by Norman Bridge provide food for thought as regards the aims of the medical profession. Bridge calls one kind of conscience the personal or individual, the other the collective or class conscience. The individual standard is perhaps the higher, but the collective or group conscience is the standard of the community or society, based on the feelings and emotions of the race, and a neglect of the collective standard to too great an extent may impair progress. What bearing has the so-called crowd or collective conscience on one's aims in medicine, the author asks, and answers by saying that with the growth of this standard the appalling record of 600,000 lives annually sacrificed to preventable diseases would dwindle into comparative insignificance. Results can come only from an awakening of the crowd conscience through education, team work, and convincing demonstration.

Medical Education.—L. F. Barker states that the greatest need of medical schools at present is that of school-controlled hospitals, in which the students can actively participate in the work of diagnosis and treatment under skilled direction, and there is probably not a single medial school in the country that has a perfectly satisfactory condition in this regard.

Sinus and Eye Disease.—W. E. Sauer describes the anatomical conditions that favor the involvement of the orbit in cases of disease of the accessory sinuses.

Eye Complications of Nasal Accessory Sinus Diseases.—A. H. Andrews describes the following complications: orbital cellulitis, dacryocystitis, lacrymal abscess, epiphora, conjunctivitis, corneal ulceration, and muscular imbalance.

Sinus Diseases.—J. H. Bryan discusses the operative treatment of suppurative sinus diseases producing orbital complications.

Gangrene of Finger.—O. F. Schussler and M. A. Stern report a case of this condition caused by the application on a closed dressing of a 5 per cent. ointment of phenol.

Institutional Hydropathic Treatment as Compared with Spa Treatment for Certain Types of Invalids. T. D. Luke.
A Case of Complete Gastrectomy. R. G. A. Moynihan.
After-Care. H. W. McConnel.
Excessive Local Perspiration. An Account of the Successful Treatment of Fifteen Cases. A. H. Pirie.
A New Form of Trochiscus. Sir James Sawyer.

Psychoneuroses.—E. D. Macnamara states that the psychoneuroses are not, as their title might lead one to expect, affections combining the symptomatology of the psychoses with that of the neuroses, but, in fact, form a sub-group of the psychoses in which the clinical phenomena are non-mental, but in which those phenomena have been produced by incidents in the mental life of the patient.

Radium Emanation Therapy.—W. Engelmann alludes to the increasing interest displayed by German clinicians in this form of treatment, which is administered by three different methods: by the drinking of radioactive water, by bathing in the latter, and by means of inhalations. The conditions for which the treatment is indicated include gout, chronic rheumatism, sciatica, neuralgia, neuritis, as well as exudates and growths which need energetic means to promote absorption.

Institutional Hydropathic Treatment.—T. D. Luke discusses the advantages of this method of treatment as compared with spa treatment.

Complete Gastrectomy.—B. G. A. Moynihan reports the later history of a patient on whom he had in December, 1907, performed a complete gastrectomy for carcinoma. The patient was perfectly well until the early part of 1910, when he began to show evidences of a profound anemia. In January, 1911, he died. Autopsy showed a complete absence of any recurrence or dissemination; the very profound anemia; and absence of any striking jejunal dilatation at or near the site of anastomosis.

After-Care.—H. W. McConnel emphasizes the necessity of looking after a patient and his surroundings after he has left a sanatorium or hospital.

Excessive Local Perspiration.—A. H. Pirie states that excessive local perspiration cannot be classed as a disease, but to one afflicted with it it is a real infirmity. A surgeon with perspiring hands runs a risk of infecting a wound. A physician with perspiring hands leaves his patent's wrist wet after feeling the pulse, and has the chagrin of seeing his patient drying the wrist. When the armpits are affected clothes are soiled and rotted by the perspiration, and the patient is uncomfortable from wearing wet underclothing. Cold feet from socks wet with perspiration is another form of annoyance. All these conditions can be cured by *x*-rays. In the author's experience every case which has been fully treated has been a complete success, and he can thoroughly recommend the treatment. When the treatment is perfectly carried out the patient suffers no discomfort and there are no bad after-effects.

A New Form of Trochiscus.—Sir James Sawyer calls attention to a new vehicle for the preparation of medicinal trochisci, which he has found useful in practice, namely, the "chocolate cream."

Acromegaly and Dystrophia Adiposo-Genitalis.—In the course of an article on tumors of the hypophysis Melchior discusses the two trophic affections which result from such neoplasms. The former has never yet been known to occur save as a result of adenoma of the hypophysis. It is too well known to be discussed in detail and only a few salient points require mention. The patient sometimes first consults the eye specialist for the pressure symptoms which may first be manifested in that organ. Females sometimes seek the gynecologist for the characteristic suppression of the menses. Hence both these specialists should be on the alert to recognize the incipient case. The course of the malady shows the widest variation and is eminently chronic—so much so that an acute case so-called does not end fatally inside of three years. At present the view of Benda that acromegaly is due to hypersecretion of the anterior lobe of the hypophysis has not been seriously controverted. The other syndrome—dystrophia adiposo-genitalis—seems the antithesis of acromegaly and is believed to be due to hyposecretion of the same lobe. It has been known since 1901 and consists of a form of infantilism, but the latter does not result necessarily from any arrest of development since it appears as a rule in the thirties or forties and is therefore retrogressive in character. There is a general accumulation of adipose side by side with atrophy of the genitals and abolition of their function. When the condition appears before puberty the latter state never supervenes. The actual causes of this syndrome appear to be sarcomas or cysts in the region of the duct. That is to say, this dystrophy, unlike acromegaly, has nothing specific about it. The patient resembles a castrated subject or a victim of myxedema and like these should be favorably influenced by organotherapy.

Pituitrin as an Oxytocic.—Stern has used hypophysis extract in several cases in which an oxytocic action was indicated. The first was an example of severe pulmonary and laryngeal tuberculosis in which it was desired to induce premature labor for the sake of both mother and child. Six mgs. of the extract were injected, the woman being in the thirty-sixth week of gestation, doubtless twins. Twenty minutes after the injection labor pains began and lasted two hours, the os becoming patent to two fingers. A second injection had a similar result, and a third and fourth were given before the uterus was evacuated. Two infants were born living and nonasphyctic. In a second case of the same character labor was induced in the thirty-second week but the injections did not accomplish the desired result and metreurysis was required to complete the dilatation of the cervix. In a third case, a nephritic, the extract was sufficient to dilate the cervix, between three and four days being required for the purpose.

Pituitrin in Obstetrics.—Bondy, like Hofbauer and Stern, is somewhat enthusiastic over pituitrin as an oxytocic. He has used it in eight cases in which labor was tedious from weakness of uterine contractions. While labor had lasted an average of 36 hours before the injections the latter caused evacution of the uterus in about half an hour (from 10 minutes to an hour). The long period before the injection corresponded naturally to the opening of the cervix while the brief period after injection agreed in a measure with the second stage of labor, but even at that the latter lasted but a quarter of the usual interval and the stage of dilatation was two or three times the average length.

August 8, 1911.

Peroneus Phenomenon as Evidence of Spasmophilia.—Lust lays great stress on the presence or absence of this phenomenon in the diagnosis of tetany in children. It may be present when other specific tests give negative results. The author naturally relies on the incidence of laryngospasm, eclamptic attacks, increased cathodic excitability, the facialis phenomenon, etc., as far as practicable; but in so-called latent spasmophilia, as evidenced by the negative result of these standards, he finds the peroneus phenomenon almost invariably present. Although it may be the sole evidence of spasmophilia, the author is not inclined to belittle its significance. He rates it as much more conclusive than either Trousseau's or Chvostek's sign. In fact if he fails to obtain this sign he would exclude spasmophilia. The peroneus sign seems to have been elaborated independently by the late Prof. Escherich and the author. It rests upon the question of the increased mechanical excitability of peripheral muscles. Other pediatrists had noticed the association and naturally the facialis phenomenon is of the same type.

Labor and Anaphylaxis.—Von der Heide seeks to bring the inauguration of labor under the head of anaphylactic phenomena. This view is based largely on animal experiment. The maternal organism becomes anaphylactic to fetal serum, so that the latter acts as an oxytocic. This line of argument is in full harmony with the anaphylactic origin of eclampsia.

Anaphylactic Phenomena in the Cornea.—Wessely, who has experimented on the rabbit's cornea, concludes that the latter is peculiarly susceptible to anaphylactic influence, despite, or because of, the natural sluggishness of its metabolism. Parenchymatous keratits he regards as an anaphylactic phenomenon. He asks: "may a general supersensitiveness develop as a result of corneal anaphylaxis?" and "given a general anaphylaxis, may the cornea participate to the extent of giving a local reaction?" Experimenting on the rabbit's cornea with heterologous serum, he finds that, after securing a reaction in one cornea, an injection into the opposite cornea—after an interval of two weeks—causes a violent reaction which shows plainly that a general anaphylaxis must have been set up.

Experimental Causation of Malformations of the Eye.—Pagenstecher has studied the effects on unborn rabbits of feeding the mothers with naphthalin. After many failures he succeeded in causing congenital cataract. He gave the drug throughout gestation at about regular intervals. All forms of cataract were noted—stratified, central, capsular, cortical, etc. Malformations were also produced in the lens, cornea, etc. The animals seemed otherwise healthy. The author lays great stress on the significance of his work, for he claims to have shown that malformations may have a purely toxic origin, and that such terms as "anomaly of the germ plasm" can no longer be used indiscriminately to explain the origin of congenital defects.

Fate of Sanatorium Consumptives.—Reiche has traced the outcome of a large number of patients treated between 1895-1904 as far as 1910. So many questions come up as to the condition on admission, length of treatment, state when discharged, etc., that figures might in general be very misleading. It appears that the death rate for those admitted year by year shows a steady decline, which of course might be due largely to increasing care in the selection of cases. The percentages of those able to earn their living show a steady increase, and this, too, might be thus explained. Nevertheless, the figures must admit of a favorable construction.

Inheritance of Disease.—Pick discusses Mendelism in relation to disease and states that thus far the material available is not in shape for use. We know that whites and negroes give rise to mulattoes, but cases are said to occur in which one negro mother has borne to a white father a white child, a black child, and a mulatto. Biometricians claim that by application of their methods the seemingly white and black offspring in such cases may really be shown to be mulattoes. In other words Mendelism is a matter of illusional resemblance and not of facts. Questions of this sort have a decided medical interest, for true hybrids tend to short life and infertility, while the pure offspring of a mixed marriage should be free from these handicaps. The chief interest of Mendelism in disease must consist largely in the great and ever-increasing number of multifamilial diseases and malformations. Many of these have already been studied from the Mendelian point of view, and, generally speaking, the influence of such a factor as Mendelism is qualitatively apparent, but when we seek quantitative ratios we are doomed to disappointment. The number of factors which might interfere with these ratios is large. Phenomena encountered may be explained in various ways. Given a multifamilial disease or deformity, no one would be able to prophesy offhand the incidence of the affection in a given brood of children. We do know that transmission along the line of six is often an assured fact.

Lead Poisoning.—Straub discusses the general subject of chronic intoxications with special reference to plumbism. As a result of animal experiment he concludes that the mineral is first deposited in a given locality from which it slowly and continuously enters the blood and attacks structures which are physiologically sensitive to its action. Injected into the muscles of animals, the drug, after absorption and on its way to be excreted, is capable of causing the most varied nervous disorders. These range from neuritis of motor nerves to paralysis of the bulb; while, between the two, numerous forms of myelitis are in evidence. The phenomena are almost entirely functional in nature. In rare instances an anatomical substratum was found. Lead poisoning at present means a supersensitiveness of nervous tissues to the action of this metal.

Bacterial Calculi in the Kidney Pelvis.—Neumann relates the case of a young woman who appeared to have developed a puerperal parametritic abscess or pyelonephritis, or both, on the right side. The symptoms subsided without the need of recourse to exact methods of diagnosis. Two months later she returned to the clinic with what might have been a high degree of acute pyelonephritis. The evidences of calculus formation were negative throughout, but it was surmised that bacterial concrements had formed and that the condition of the kidney pelvis was due rather to calculi than to an essential pyonephrosis. This conclusion was reached chiefly through the history of the patient, which pointed to renal calculi in girlhood. An operation confirmed the justice of the surmise. The kidney itself was practically normal. Pyelitis was present along with concrements of a peculiar character, resembling gallstones. These were shown to consist of the *Bacillus coli*. Such a state of affairs is so notably rare that its nature must be obscure. The author knows of but three recorded examples and these throw little light on his own case. Other material exists, not classed specifically under this head but perhaps best explained thereby. The author assumes that some of these cases are of hematogenous origin, since they cannot be explained by a urogenous theory. We can only infer that, while bacterial calculi may form in the kidney pelvis, their relation to suppuration is far from clear. They are assumed to be secondary to pyelitis, yet there may be nothing to account for the latter, while there may also be a history of kidney stones.

Pneumothorax from Pulmonary Echinococcus: Differential Diagnosis from Tuberculosis.—Patella presented the case of a young man operated upon for pulmonary disease caused by the presence of echinococcus in the right lung, which by rupture had produced a pyopneumothorax with extensive pulmonary atelectasis. This is the third case seen by him caused by the rupture into the pleural cavity of an echinococcus cyst. He advocates early diagnosis in order that the operation which is demanded by the condition may be done early. If the condition is caused by tuberculosis the treatment should be quite different. The differential diagnosis points are as follows: Residence in a region where the echinococcus infection is frequent; biological examination of the blood; eosinophilia; urticarial eruption after the occurrence of the pneumothorax; occurrence after exertion after the forma- of hydopneumothorax, due to the emptying of the contents of the cyst into the pleural cavity; slow appearance of pus in the fluid due to the relative aseptic condition of the lung.—*La Riforma Medica.*

Insurance Medicine.

A "Conservation Department" has recently been established by the Equitable Life Assurance Society, an object of which is, in conjunction with the Medical Department, to assist by educational and perhaps other methods in the conservation of human life. In a letter outlining the aims of this movement, Dr. Franklin C. Wells, Medical Director, calls upon the examiners of the company for such support and assistance as they are in position to give. Since, he says, the examiners are in touch with the leaders of public opinion, and with the most influential elements of the communities in which they reside, they are in a position to render invaluable service to the policyholders of the company and to humanity in general by urging active support of official and unofficial movements and measures wisely designed to conserve human life. The medical profession and public health officials should be backed by a strong and intelligent public sentiment in their efforts to secure improved health conditions, and it is the intention of those in charge of this department, by every consistent means of publicity, to stimulate and develop this sentiment in support of the public service rendered by the medical profession. It is not intended to enter into the consideration of treatment or remedies, but efforts will be directed solely along the lines of prevention. As a means to this end, Dr. Wells says that policyholders and the public in general, in order to get the full benefits of the science of preventive medicine, should get in the habit of going to their family physicians for health examinations with reasonable frequency, in order that the doctor may have an opportunity to guide them into healthful modes of life and to detect disease in its incipient stages when it may be checked or cured, and further, while taking no part in any contention as to the merits of the different schools of medicine, or the various methods of relieving or curing disease, the department is opposed to quack remedies and unwholesome nostrums which do much harm and are chiefly designed to draw financial tribute from human weakness and ignorance, and the society will advise its members accordingly.

National Insurance.—G. P. Forrester describes the system of national insurance as established in Germany, and presents the following data based on the imperial statistics for 1909: Of a total population exceeding 63,000,000, there were 12,519,785 persons insured against sickness. The average expenditure for medical attendance for each head of the insured amounted to $1.43, or an increase of 165.1 per cent. since 1885, when it stood at 54 cents. The payments to hospitals on behalf of insured persons averaged 83 cents for each head, again an increase amounting to 122 per cent. since 1892. The average incidence of sickness coupled with incapacity for work and therefore necessitating the payment of sick pay amounted to 40.3 per cent. of all persons insured, the figures being 42.2 per cent. in the case of males and 35.2 per cent. for females. The average duration of each case of illness of this kind was 20.5 days, or 19.4 days in the case of males and 23.8 days for females. This difference is interesting. The mortality among the insured amounted to 0.75 per cent., and reckoned for the male members the percentage of deaths was 0.81, and among the females 0.58. The average cost for drugs and appliances amounted to 89 cents for each person insured, an increase of 110.1 per cent. since 1885.—*New York Medical Journal*, August 19, 1911.

Injury or Carcinoma of the Pancreas?—Stempel gives in detail the history of a patient who died six weeks after a fall. At autopsy a very soft pancreas, surrounded by adhesions, was found, and carcinoma of the organ diagnosed. No microscopical examination was made. Accident indemnity was accordingly refused. An expert called in on appeal of the widow pointed out the impossibility of final decision because of incomplete history and autopsy. Because of the previous good health of the patient, the absence of jaundice, the softness of the pancreas, the absence of metastases, etc., another expert thought that hemorrhage into the pancreas with consequent necrosis was the more probable explanation, and a corresponding settlement was made in regard to indemnity.—*Zeitschrift für Versicherungsmedizin*, March, 1911.

Proof of Simulation of Unilateral or Bilateral Deafness.—Müller says that one ear may be made insensitive to other sounds, if a continuous loud noise is made just in front of it or within it. Bárány has constructed a clockwork for the production of such a noise. Voss simply sends a stream of air into the ear, while Müller uses the instrument constructed for vibratory massage of the ear drum, applying the apparatus not completely air-tight to the ear. If a normally hearing person is asked to read aloud, and a noise as described above is suddenly produced in both his ears, his voice at once becomes louder. He loses for a while the ability to judge the intensity of the voice. If his ears are simply shut by the examiner's fingers, his voice becomes lower. When a person complains of unilateral deafness, he is made to read aloud and suddenly a noise is produced in his good ear. If the voice does not become louder, the deafness is simulated. If bilateral deafness is alleged, no change in voice should take place when a sudden noise is produced in both ears. This method disposes of all necessity of cooperation on the part of the patient, or of speaking to him at all, and thus is free from subjective influence.—*Zeitschrift für Versicherungsmedizin*, March, 1911.

Physicians and Agrarian Reform.—Eisenstadt discusses the agrarian reform views of Ebeling and points out why physicians should be interested in the problem. Economically they belong to the middle class, and it is in their interest not to lose too much of their income as rent. Physicians, too, are unpaid officers of the state, for they furnish birth and death certificates, notify the governmental bodies of the existence of infectious diseases, serve in hospitals, give free advice to poor patients, etc. The government should return in kind by making such land regulations as would ease their rent burden. Social conditions, too, are at the bottom of much infectious disease, and reform in this respect should be welcomed by physicians, who are directly interested in the health of the community. The author states various other reasons why such a reform propaganda as that of Henry George should find adherents among the medical profession.—*Zeitschrift für Versicherungsmedizin*, March, 1911.

The First Line of Defence in the Workmen's Compensation Act.—R. J. Collie presents a somewhat elaborate criticism of the British Workmen's Compensation Act, or rather of parts of it, and especially of those parts which affect insurance companies. The act embraces every kind of employment, including persons engaged in clerical work up to a certain point. No fewer than 20,000,000 people come under it. It is therefore obvious that from a commercial point of view employers must see to it that they engage young and healthy workers. The majority of employers insure against the risk of financial loss in case of accidents with insurance companies, by paying a premium which covers the employer's risk. Collie points out many defects in the act from the medicolegal standpoint and strongly advocates that all candidates for employment should undergo a medical examination. It may be said that insurance companies in Great Britain have entered into an agreement with the Home Office to exercise no discrimination and not to reject workmen over sixty years of age, but they can fix any premium they may think fit.—*Transactions of the Life Assurance Medical Officers' Association*, London, 1910.

A London School Clinic.—M. D. Eder states that gen-

eral dissatisfaction has arisen when the doctor's work in the schools has been limited to inspection. Medical inspection may do well enough for the unborn children of the next generation or the one after, but it will not help those who are going to school just now unless inspection is supplemented by medical treatment. The existing agencies for furnishing this are the private doctor and the voluntary hospital. The private practitioner does not meet the case because in England the people receive an insufficient wage to pay the doctor decently. Those defects which the author especially considers require prolonged or skilled treatment, or both. Some diseases may require treatment for months; other diseases, such as ringworm, may require special instruments; defects of sight require accurate testing. As regards hospital treatment, when this involves regular visits over a long period of time, it is noted that a journey to the hospital involves much loss of time to the parent; much loss of time for the child; much loss of time for the teacher; and considerable expense. Moreover these cases are not welcomed at the hospital. There are too many of them and they are not exciting. The inadequacy of these agencies is shown by the fact that in Bradford, despite fifteen years of medical inspection, the majority of the children remained untreated. The author describes the types of clinics that have been established in England to furnish adequate treatment for the children of the poor. First the clinic, as the one established at Poplar, in the school itself. Second, the centralized clinic, exemplified by the one at Bradford, to which center the children come from all the schools to be treated. In London it has been found best to establish several local clinics receiving the children of adjacent schools. The school clinic is able to do little for very delicate children—for those suffering from severe anemia, enlarged glands, chorea, pulmonary tuberculosis, and heart disease. The cases especially adaptable are eye defects, external or internal; ear discharges; skin diseases, including ringworm; adenoids, enlarged tonsils, and other causes of mouth-breathing; dental diseases; slight spinal curvatures, and similar deformities. In one of the school clinics, of 338 cases, 264 have improved or have been cured. Cases requiring operation are sent to some hospital. The treatment is entirely voluntary. The parents are not threatened with a fine or other form of punishment if they do not look after their children's defects. They are notified in writing that these defects are present and are asked to sign a consent to have these defects remedied. They are then requested to accompany the child to the school clinic at a certain hour on a specified day. Consent is granted in almost every case. Parents do not require coercion; if the facilities are provided, the parents will gladly avail themselves of these. At Deptford, one of the local school clinics of London, the following forms of treatment are carried out: dental treatment, treatment of diseases of the skin, nose, throat, and eyes; remedial drills for spinal curvatures, and for postoperative cases. Out of 365 children examined at Bradford, 94 proved to be in an infectious condition and unfit for school attendance. The following is the estimate of the annual cost of a school clinic: Nurse, $565; two doctors, each devoting two half-days each week to the clinic, $500; dentist, whole time, $1,500; teacher, $250; caretaker, $200; rates and taxes, $60; drugs, $100; sundries, $100; rent, $215. The total expense is $3,500. Over 2,000 children can be treated by the medical staff yearly, working two half-days a week, and at least 3,000 children by the dentist, working full time.—*The British Journal of Children's Diseases,* May, 1911.

Phenolsulphonephthalein Test in Estimating Functional Activity of the Kidneys.—Charles Goodman notes the difficulty attending any method of determining the index of capacity of the kidney. One of the recent methods involves the use of phenolsulphonephthalein, which is administered by preference subcutaneously, a dose of one-tenth of a grain being injected into the arm. In a healthy individual the drug appears in the urine in from three to ten minutes after administration. It is possible to measure the amount excreted. The drug is eliminated only by the kidneys, and in healthy people from 60 to 70 per cent. is recovered at the end of two hours. No reaction occurs eight hours after the injection is given. In pathological conditions of the kidney the excretion of the dye is considerably delayed. The author reports cases in which he has found the test of distinct clinical value. One of these was a case of multiple calculi of the left kidney with a calculus impacted in the right ureter. Administration of one-tenth of a grain of phenolsulphonephthalein was followed by the appearance of only traces of this drug from the left kidney at the end of two hours. In cases of enlarged prostate it was possible to determine the functional capacity of the kidney preparatory to operation. The test was also valuable in chronic interstitial nephritis, from the viewpoint both of diagnosis and treatment. The author states that it is possible to measure accurately the amount of drug eliminated. In a case of diabetes insipidus the patient passed 1,150 c.c. of urine within two hours and the drug recovered showed almost the entire amount of the dye. The presence of pus or other matter does not interfere with the estimation of the amount of drug recovered. The technique is as follows: The injection is given, the time noted, and the patient is asked to void urine every five minutes in order that one may establish the time when the drug first appears in the urine. Or the patient may be catheterized at the end of the first hour and also at the end of the second hour, and the amount of drug eliminated is accurately measured. The drug may be identified in the urine by its brilliant scarlet color in alkaline solution, the alkalinity being obtained by the addition of a few drops of sodium hydroxide in solution.—*American Medicine,* May, 1911.

Reporting of Accidents by Physicians.—In Wisconsin physicians are required by law to report to the Bureau of Vital Statistics all accident cases coming under their care, but the observance of this law is not at all general among the physicians of the State.

The Development of Life Insurance in Germany.—The following figures show the growth of life insurance in Germany:

Business Year.	Amount of Insurance (in million mks.)	Business Year	Amount of Insurance (in million mks.)	Business Year	Amount of Insurance (in million mks.)
1897	509	1901	561	1905	772
1898	535	1902	572	1906	859
1899	551	1903	647	1907	935
1900	554	1904	713	1908	941

Business Year.	Number of Policies. Maturing Through Death	Amt. (in million mks.)	Business Year.	Number of Policies. Maturing Through Death	Amt. in million mks.)
1902	22,992	89	1906	24,535	106
1903	24,193	96	1907	25,920	108
1904	25,289	100	1908	27,277	120
1905	26,016	105			

At the end of the year 1908 there existed in Germany 2,066,743 insurance policies for the sum of 9,700,888,852 marks.— *Blätter für Vertrauensärzte der Lebensversicherung,* January and February, 1910.

A Trap for a Malingerer.—The *British Medical Journal* states that in the Marylebone County Court a man claiming compensation for personal injuries said that in consequence of his collarbone having been broken, though reunited, he could not close his fist, and his grasp had become less firm. He was called up to the bench beside His Honor (Sir W. Lucius Selfe). Dr. Oldfield, for the Accident Insurance Company, directed the applicant to place his left hand in the judge's right, palm to palm, push his own right hand well into his trousers pocket, and stand tiptoe on both feet. Having assumed this position, the surgeon gave him a slight push forward, and, to save himself from falling, the claimant clinched the judge's fist so firmly that His Honor squirmed, and called out, "That grip is firm enough," at which there was much merriment.

Book Reviews.

HIERONYMUS FRACASTOR'S SYPHILIS, FROM THE ORIGINAL LATIN. A Translation in prose of Fracastor's immortal poem. Price $2.00. St. Louis: The Philmar Company, 1911.

THE treatise on syphilis in Latin hexameters was first published by Fracastor in 1530 and at once attracted attention, not only as a medical treatise on a new and terrible disease, but as a creditable literary production. The present prose rendering is excellently done, and the publishers have rendered a service to literary medicine in putting it forth. It is printed on hand-made paper, with buckram library binding. It is a pity that the original poem was not reprinted in the same volume, for it is difficult to obtain, and many physicians would be glad to possess it.

THE HUMAN ATMOSPHERE, or The Aura Made Visible by the Aid of Chemical Screens. By WALTER J. KILNER, B.A., M.B. Cantab., M.R.C.P., etc., late Electrician at St. Thomas' Hospital, London. Illustrated. Price, $4.00; with Colored Screens, $9.00. New York: Rebman Company, 1911.

THIS is an odd but very interesting medical book, one that would suggest occultism, except that the author employs colored screens to prepare the retina for the strange things that it is to see, just as Baron Reichenbach employed absolute darkness to sensitize the retina so that it could see the light rays emanating from a magnet. The author claims that every person is surrounded by a mist or aura varying in density and thickness in different individuals, at different ages, and in different conditions of health. This mist is ordinarily invisible to the normal eye, but the eye can be so sensitized by gazing for a certain period through a thin layer of a solution of dicyanin that the aura becomes visible. Space forbids a description of the aura or the changes which it undergoes in varying stages of health and disease. The reader is referred to the book itself for such description, and doubtless he will be interested not only in reading what the author so confidently states but in trying for himself to see the aura of his patients and friends, with or without the screen. The reviewer will confess that he has not been able to see the aura as depicted by Dr. Kilner, but possibly that was because he failed in some particular to follow the author's directions. The aura, as described, is very similar to the appearance described in theosophical books, in which there is the etheric double next the body, surrounded by the astral body. The book will therefore no doubt be welcomed by occultists as furnishing scientific evidence—or shall we say evidence of a scientific man—of the truth of one part of their age-long teachings.

THE MEDICAL DISEASES OF CHILDREN. By REGINALD MILLER, M.D. (Lond.), M.R.C.P., Physician to Out-Patients, Paddington Green Children's Hospital; Lecturer in Pharmacology and Therapeutics, St. Mary's Hospital Medical School; Late Medical Registrar and Pathologist, Hospital for Sick Children, Great Ormond Street. Price $4.00. New York: William Wood & Company, 1911.

IT would be impossible within the limits of a short review even to indicate all of the excellent features of this book. Written primarily as a teaching manual, available for both student and practitioner, it presupposes a working knowledge of the diseases of adults, and dwells particularly upon the phases and peculiarities of disease as manifested in children. The omission therefore of the mass of details on disease in general that is found in most textbooks on pediatrics enables the author to present the subject matter in a form that is both compact and complete, and to include accurate descriptions of practically all of the most recent contributions to pediatric science, such as the diseases of Meckel's diverticulum, congenital acholuric jaundice, adrenal hemorrhage, adrenal hypersecretion, cleidocranial dysostosis, the various clinical types of acidosis and acid intoxication, etc. One original feature of this book is the classification of infective diseases according to the infecting organism, thus anticipating the time when this method of classification will predominate in all textbooks on medicine. Thus, under pneumococcal infection are taken up in order the subjects of pneumococcal pneumonia, pleurisy, empyema, pericarditis, endocarditis, meningitis, peritonitis, nephritis, etc. The same plan is followed with the other types of infection. The rheumatic group is presented in a manner that helps to clear up many misty conceptions regarding this type of infection: the significance of subcutaneous nodules, of rheumatic pleurisy and pneumonia, the non-rheumatic character and separate identity of erythema nodosum, the close relationship between rheumatism and rheumatoid arthritis are all thoroughly described. The subject of differential diagnosis is presented fully and clearly. An example of this is illustrated in the diagnosis of intussusception from intestinal colic, acute ileocolitis, Henoch's purpura, and invagination of Meckel's diverticulum. There are numerous excellent photographic illustrations and comparative tables, both of which contribute to the didactic value of this book. The typography and binding leave nothing to be desired.

REMEDIAL GYMNASTICS FOR HEART AFFECTIONS, used at Bad-Nauheim, being a translation of "Die Gymnastik der Herzleidenden" von Dr. Med. JULIUS HOFMANN und Dr. Med. LUDWIG PÖHLMAN, Berlin und Bad-Nauheim, by JOHN GEORGE GARSON, M.D., Edin., etc., Physician to the Sanatoria and Bad-Nauheim, Eversley, Hants, with Fifty-one Full-Page Illustrations and Diagrams, $2 net. Paul B. Hoeber, 69 East 59th Street, New York, 1911.

THIS small book of 128 pages, of which less than one-third is text, is a compendium of instructions for carrying out the Bad-Nauheim treatment of remedial gymnastics for heart affections. The translator made himself familiar with the author's methods and sanatorium, which, of course, are founded on those originated by the late August Schott, who did the work of elaborating these "resistance exercises" into a system of therapeutics.

Three such systems of remedial gymnastics are alluded to, that of the Austrian Herz, the exercises of the Swedish Zander and those developed by Schott. A fourth, the Oertel Terrain method, is mentioned to show its inappropriateness to most cases; for the walking (up hill) a definite time may place the patient unfortunately when the fatigue, indicating rest, overtakes him and he is far from home.

The CO_2 bath feature of the treatment is discussed adequately; the collateral action of diet and waters, stimulants, breathing, etc., is considered; the indications and details of method are covered and the testing of results on the patient is properly valued. Emphasis is well put upon the necessity of medical supervision, for the subject is not one for the patient himself to apply, and therefore the book is one distinctly for the physician. The plan of representing the exercises by a full page illustration of each, shows the operator with the patient and gives a brief note of instruction. These constitute more than two-thirds of the treatise. It is a helpful handbook for the physician wanting to apply the treatment, and this would be more often done here, without the difficulties encountered in advising a trip to Germany, if Americans physicians were more familiar with the method, knew its field in therapeutics ("initial heart disease, not advanced arteriosclerosis nor chronic nephritis") and how easily it could be carried out at the patient's home.

EINFÜHRUNG IN DIE EXPERIMENTELLE THERAPIE. Von Dr. MARTIN JACOBY, fr. a. o. Professor der Pharmakologie a. d. Universität Heidelberg; z. Zeit Leiter des biochemischen Laboratoriums am Krankenhaus Moabit, Berlin. Berlin: Julius Springer, 1910.

IN the presence of the flood of medical textbooks, that make choice and recommendation an exceedingly difficult task, the reviewer is seldom warranted in saying, "Here is a book for which there has been a need." With the unexpected results that have been obtained by experimental therapeutics during the past few years, almost every physician has felt the necessity of acquainting himself more thoroughly with the elements of this subject. The practising physician in his time has had no course of lectures on this subject as a part of his curriculum, and even the student of to-day has the opportunity, in a few universities, to attend one lecture on a single theme of this broad domain. The weeklies alone are left, and these are naturally deficient in providing the necessary explanations. The author has endeavored to fill this gap, and he has done so with unusual success. That the entire subject has been exhaustively covered is indicated by the headings of the various chapters: Immuno-, sero-, chemotherapy, therapy of neoplasms, inflammation, diseases of the blood, diabetes, gout, fevers, circulatory disturbances, derangements of the gastrointestinal canal, the therapy of fatigue, the therapy of chemical and functional antagonisms, and substitution therapy. Within the limits of only 174 pages the author has succeeded in presenting with exceptional precision and forceful language a clear survey, such as investigators who completely control their subject, are capable of doing. The compactness of the book, and the plainly evident effort of the author to make its therapeutic value in practice the final goal in every piece of work, both combine to make this book a welcome one to the busy practitioner.

L'Anaphylaxie. Par Charles Richet, Professeur à la Faculté de Médecine de Paris. Price 3 fr. 50. Paris: Félix Alcan, 1911.

This volume is a succinct review of the many recent contributions that have been made to the subject of anaphylaxis. The author was the first one to describe this important phenomenon and it was he who invented the term anaphylaxis. It is noted that as long ago as 1839 Magendie observed that rabbits that had been injected with albumin were unable a few days later to tolerate a similar dose. Nevertheless the significance of this phenomenon was not understood until Richet's contribution in 1902. In this book the author describes in detail his own experiments and those of numerous other workers, and presents an extensive bibliography. In therapeutics, legal medicine, and hygiene, as well as in general biology, anaphylaxis plays an important rôle requiring exact information.

Bismuth Paste in Chronic Suppurations. Its Diagnostic Importance and Therapeutic Value. By Emil G. Beck, M.D., Surgeon to the North Chicago Hospital, Chicago, Ill. With an Introduction by Carl Beck, M.D., and a Chapter on the Application of Bismuth Paste in the Treatment of Chronic Suppuration of the Nasal Accessory Sinuses and the Ear, by Joseph C. Beck, M.D. With Eighty-one Engravings, Nine Diagrammatic Illustrations, and a Colored Plate. Price, $2.50. St. Louis: C. V. Mosby Company, 1910.

The use of bismuth paste in surgery has passed beyond the experimental stage. This monograph presents the subject in its present state of development, bringing it within the reach of the general practitioner, who can easily avail himself of its simplicity of technique in a multitude of conditions. The uses of bismuth paste are considered in detail as follows: in anatomical diagnosis; as a means of revealing diagnostic errors; its therapeutic effects; the treatment of sinuses due to spondylitis, and those following osteomyelitis, joint diseases, and abdominal and kidney operations; the diagnosis and treatment of rectal fistulæ; the treatment of fecal fistulæ, empyema, and lung abscess; the conservative treatment of cold abscesses; the limitations and causes of failure; bismuth poisoning and its prevention; bismuth paste in the treatment of chronic suppurative diseases of the nose; accessory sinuses, ears, and mastoid process, and its use in dentistry. This summary of its contents fully indicates the usefulness of this book.

Die Massenverhältnisse des Herzens Unter Pathologischen Zuständen. Pathologisch-Anatomische Untersuchungen. Von Sofus Wideroe. Zwei Tafeln, 1 Textfigur, 17 Kurven. Christiana: In Kommission bei Jacal Dybwad, 1911.

In the experimental investigation described within the pages of this monograph the object of the author was to study the gross features of cardiac hypertrophy and dilatation. The reaction of the heart in various pathological conditions of other organs was studied by measurement of the cardiac chambers, and the results are indicated by means of graphic charts.

Urine Examination Made Easy. A Plan of Examination With the Common Tests Fully Described. By Thomas Carruthers, M.D., M.B., Ch.B. Second edition. Price, 60 cents. London: J. & A. Churchhill; Philadelphia: P. Blakiston's Son & Co., 1911.

This little manual of 47 pages is made up of notes that were supplied to nurses with the view of simplifying their study of urinary analysis. The entire subject is reduced to its simplest terms. The various tests are described in schematic form. This book should prove helpful to students as a means of rapidly reviewing the subject.

The General Practitioner as a Specialist. A Treatise Devoted to the Consideration of Medical Specialties; a guide to the development of office practice. By Jacob Dissinger Albright, M.D. Fourth edition, revised, enlarged, and illustrated. Price $3.00. Philadelphia: Published by the Author, 1911.

Why general practitioners should want to become specialists we do not know, nor does the reason become more apparent after perusal of this volume. Several subjects are "treated" in this book, presumably after the manner that obtains among specialists, but in the limited space at our disposal we can only draw attention to a few of the specialists' stunts. In the chapter on Hernia there is no reference that we can find to Bassini's operation or to any of its modifications, but there is much on trusses and injection fluids, and, incidentally, both are manufactured by the author of this book. In dealing with cancer we find nothing that can aid in an early diagnosis and consequent removal of the tumor, but a paste or plaster or cure for nearly every letter in the alphabet. There are some pages on the "Philosophy of Orificial Surgery"; it is all philosophy, the surgery or practical part seems to have been omitted; probably the loss is but small. The chapter on Mental and Magnetic Healing ("A Complete Exposition of Vital Magnetism, Suggestion, and Mental Therapeutics; the Basis of All Popular Pathies, and the Essentials of All Courses of Instruction on These Subjects") was "sold to physicians and others for fifty dollars." Now physicians and others can obtain it for a paltry three dollars. This chapter contains some rare therapeutic gems; for example, "Mental effort is a complete panacea for constipation"; we can quite believe the possibility of this if the unfortunate sufferer paid fifty dollars for the "mental effort"; but now that its price has been reduced the chances are that the efficacy is reduced likewise. Further on in the same chapter we read that "cold feet may be relieved by imagining that there is a hot brick near them and repeating mentally: 'now they will soon get warm,' etc." The author does not say how much imagination it will take to heat a modern apartment. The book concludes with two chapters calculated to turn out specialists on "sexual incompetence" and genitourinary diseases. There are also several other topics, such as Tapeworms and Tobacco, Goiter and Gynecology, but the foregoing will give a sufficient idea of the book.

A Manual of Physical Diagnosis by Brefney Rolph O'Reilly, M.D., C.M. (F.T.M.C., Toronto; M.R.C.S., Eng.; L.R.C.P., Lond.). Demonstrator in Clinical Medicine and in Pathology, University of Toronto; Assistant Physician to St. Michael's Hospital, Toronto; Physician to Toronto Hospital for Incurables. With 6 plates and 49 other illustrations. $2.00 net. Philadelphia: P. Blakiston's Son & Co., 1911.

This book is an extremely useful one, both for the student and the general practitioner, as it presents a difficult subject in a simple, concise, and lucid manner. Chapters III and IV, "General Inspection" and "Special Inspection," are particularly helpful. Here the logical arrangement, which characterizes the entire book, is most valuable. The appendix describes the ordinary laboratory methods which are in use in the routine examinations of patients of St. Michael's Hospital, Toronto, Canada.

Hughes' Practice of Medicine, Including a Section on Mental Diseases and One on the Diseases of the Skin. Tenth Edition, Revised and Enlarged. By R. J. E. Scott, M.A., B.C.L., M.D., Attending Physician to the Demilt Dispensary; formerly Attending Physician to the Bellevue Dispensary, New York; Author of "The State Board Examination Series," etc., etc. With 63 illustrations. $2.50 net. Philadelphia: P. Blakiston's Son & Co., 1911.

This book has been revised, the subject matter rearranged, and new sections have been added. Four hundred prescriptions have been included in the sections devoted to treatment. The book has been well brought up to date, and while it is by no means exhaustive its very conciseness will recommend it to many who are seeking the general principles rather than the detail work.

Outlines of Psychiatry. By William A. White, M.D., Superintendent Government Hospital for the Insane, Washington, D. C.; First Lieutenant Medical Reserve Corps, United States Army; Professor of Nervous and Mental Diseases Georgetown University, Washington, D. C.; Professor of Nervous and Mental Diseases George Washington University, Washington, D. C., and Lecturer on Insanity U. S. Army and U. S. Navy Medical Schools. Third Edition, Revised and Enlarged. Price $2.50. New York: The Journal of Nervous and Mental Disease Publishing Company, 1911.

This is the third edition of the book that has appeared within a period of less than four years. It has apparently fulfilled the function of a helpful guide to students by describing in as clear a manner as possible the principal types of mental disease. The present edition is more elaborate than the former editions. The additions consist of the introduction of foot-note references to the literature, and the more extended discussion of the nature of mental disease, of heredity, and of psychotherapy. There have been added a discussion of certain additional symptoms, as the "complex" and Ganser's symptom or the symptom of approximate answers, and a scheme for a standard minimum examination of mental cases for use in hospitals. A short description of the work of Sérieux and Capgras on the delirium of interpretation and delirium of revindication, and descriptions of the psychoses of pellagra and of the compulsion and anxiety neuroses have been added.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-ninth Annual Meeting Held in Birmingham, July 26-28, 1911.

(Special Report to the MEDICAL RECORD.)

(Concluded from page 450.)

SECTION ON MEDICINE.

THE PRESIDENT, DR. A. H. CARTER OF BIRMINGHAM, IN THE CHAIR.

First Day—Wednesday, July 26, 1911.

Address of the President.—Dr. A. H. CARTER in his opening address offered a cordial welcome to both members and visitors. He thanked those who had provided papers for the occasion, especially those who prepared for the fixed discussions. He did not think the annual meeting a suitable occasion for bringing forward new theories or original work. Rather it offered a good opportunity for discussing those clinical questions which had to be answered by every general practitioner in his daily experience. This observation of the president was an appropriate introduction for the first discussion of the session, the subject of which was:

Asthma.—DR. GEORGE A. GIBSON of Edinburgh in opening the discussion began with a sketch of the general anatomy and physiology of the parts involved in respiration, noticing especially the arrangements—mechanical and nervous—for carrying on the aëration of the blood simultaneously with the respiration. He dwelt briefly too on the protective mechanism of the air tubes, the distribution of the erectile and muscular tissues in the larger and smaller respectively, and the nervous influences brought into play. The function of warming and purifying the (inspired) air in the nasal fossæ and upper tubes was mentioned and the importance of the extensive distribution of erectile tissue in this region pointed out. Then followed remarks on the nervous mechanism. It had been established that the smallest tubes contain muscular tissue and the vagi convey both constrictor and dilator fibers to them so that the finest bronchioles are under complete nervous control. With regard to the various explanations of the asthmatic paroxysm. Dr. Gibson declared that he still adhered to the theory of spasm of the finer tubes, which had been held so long by distinguished observers. This was of course brought on by some excitant of the nervous system occurring suddenly. At the same time other observers have been dissatisfied with this view and proposed very different explanations, such as spasm of the diaphragm or a vasomotor neurosis, acute exudative bronchitis, and one calling in asthenia instead of spasm of the bronchi.

Dr. Gibson then spoke of the prevailing confusion caused by careless nomenclature and read a letter by Sir Clifford Allbutt on this point. Cardiac asthma was a misnomer. There was only one true asthma, however many forms of secondary dyspnea might resemble it. The real disease was a neurosis, although other factors might be thrown in. It could be produced by a nervous excitant which could occur periodically. It had been proved by Heberden that an extosis pressing on the vagus could set up the *status asthmaticus*. Certain irritants of the nasal, laryngeal, and tracheal mucous membrane, *e.g.* fogs, pollens of grasses, etc., had long been recognized as capable of causing the paroxysms. Reflex irritants arising in the alimentary or pelvic organs were also recognized generally as excitants of the paroxysms. Some thought cutaneous irritation might be equally to blame in patients predisposed to attacks. Among the consequences of asthma must be considered the overdistention of the lungs, sclerosis of the pulmonary vessels, and dilatation of the right side of the heart, the degree of these complications of a case being largely dependent on the frequency of the paroxysms.

Treatment must be directed to the avoidance of catarrh and at the same time of digestive troubles. Dietetic and climatic influences were therefore important and were often exceedingly difficult to arrange on account of individual peculiarities. As to drugs, ether, chloroform, and atropine held the first place. Lobelia was often most effective though its influence did not last long. Nitrites had done good service. He used morphine as sparingly as possible. Cocaine was dangerous, though it was a constituent of various proprietary drugs.

Dr. ROBERT SAUNDBY agreed that the disease was a neurosis but would not unduly narrow this conception. He said asthmatics were liable to fatal anaphylaxis after ordinary doses of diphtheria antitoxin. This he seemed to think in some way analogous to bronchial irritation and urticaria after antitoxin.

Dr. SAMUEL WEST of London admitted the neurosis but asked where the irritating agent was seated. He thought epilepsy afforded an analogy with asthma. Like epilepsy true asthma mostly developed in childhood. Late cases were probably counterfeits.

Dr. WILLIAM HUNTER of London thought the spasm more important than anything. He treated most cases with potassic iodide.

Dr. STACEY WILSON of Birmingham laid stress on the reflex cases. He doubted the value of nitrites and said the spasm might be compensatory and then they would be hardly suitable even if justifiable.

Dr. WILLIAM EWART of London spoke of peripheral spasm limited to the respiratory and alimentary tracts. The great variety of types of irritants was the key to the diversity of remedies employed.

Dr. O. F. F. GRUNBAUM of London believed that some cases had been much improved by vaccines.

Dr. A. H. CARTER, president of the section, emphasized the view that true asthma was a neurosis. It might be associated with local or general instability of the nervous system. Treatment should be directed to the cause when possible, not to symptoms only.

Syphilis of the Lung.—Dr. J. DOUGLAS STANLEY of Birmingham read this paper, in which he described the lesions met with in the lung and illustrated their pathology and course by fifteen cases which had come under his observation. Syphilis might affect the lungs and pleura only, or the trachea and bronchi alone, or all together. In the tertiary stage the trachea commonly underwent ulceration, and this ulceration might go on to perforation or produce very marked stenosis. A similar condition in the bronchi often caused bronchiectasis. The early changes in the lung were an intense cell proliferation filling the alveoli and infiltrating the surrounding structures. The vessels showed the typical changes of syphilis. In certain cases there was an early diffuse sclerosis, the lung tissue being tough with great increase of connective tissue. Miliary gummata were numerous. In still other cases there was a dense sclerosis leading quite often to contraction. Large gummata might occur in syphilis of the lung, but miliary gummata were much the more common. The symptoms of lung syphilis were more definite the more chronic was the case. Hemoptysis was suggestive of slow ulceration of a bronchial surface. Cough was irregular. Fever and sweats, when they occurred, were due to a mixed infection; their presence might easily give rise to an error in diagnosis since they suggested tuberculosis so strongly.

Dr. WILLIAM HUNTER of London thought syphilis of the lung must be a very rare condition, for he had failed to find it in a thousand consecutive autopsies.

Dr. L. E. SHAW of London had never found the lesion

of pulmonary syphilis at autopsy though he had seen them in museum specimens.

Second Day—Thursday, July 27.

Obscure Cases of Fever Without Physical Signs.—Dr. Hale White of London opened the discussion on this topic. He said that it was necessary to remember that various nonmorbid causes might greatly affect the thermometer. Some simple chemicals had the property of raising the temperature to the fever point. An excess of carbohydrate food had been known to produce the same effect. So had walking or any form of physical exercise. He thought that the effect of the nervous system on the temperature was not sufficiently appreciated, especially in young patients—for the stronger they were the more easily was pyrexia induced. Fracture of the spine in the cervical region was specially considered and damage to the corpus striatum was a cause of grave pyrexia. Hysteria was also a cause of variation. The importance of examining the blood and the cerebrospinal fluid was pointed out. Sometimes an explanation of an obscure pyrexia was found in the urine even though no blood, albumin, or casts were present. Malignant disease as a cause of high temperature was often overlooked, as was also cirrhosis of the liver. Malignant endocarditis, early or latent tuberculosis, and typhoid fever were fertile sources of difficulty or error; but the most frequent mistake was that of overlooking small collections of pus. Empyema of some extent was also a frequent cause and *x*-rays were most valuable in locating it.

Sir Willliam Osler of Oxford said that a few cases were neurotic, mostly those of young people and especially fat children. There was another group of undetected tumors. A much larger number of cases were tuberculous. Although no physical signs were ascertained to be present he had found bacilli in the blood. These, with other cases, were grouped as infectious. He instanced chronic septic endocarditis, syphilis, and infectious organisms in the colon, etc.

Dr. E. C. Hort of London advocated the doctrine of the unity of fevers. This was based on the theory that cell destruction would always set up pyrexia. The absorption of the detritus of the dead cells excited the febrile reaction. He showed diagrams to illustrate this view.

Dr. Tyson of Folkestone remarked that in toxemic conditions the respiration rate should be watched, as it often indicated abnormality when the temperature was normal. The age and sex of the patient were also both important points.

Dr. Stacey Wilson of Birmingham believed in raw meat feeding, combined with antiseptics, such as the sulphocarbotates, which he alternated with quinine, in the treatment of rheumatic pyrexia.

Dr. Rudolph of Toronto had made experiments from which he concluded that Wunderlich was right in regarding the normal temperature as a rather elastic point, varying between 97.2° F. and 98.8° F.

Dr. Hobhouse of Brighton said that in children a slight rise of temperature might be physiological—a mere hastening of metabolism. A few cases were never explained, even in the post-mortem room.

Dr. C. O. Hawthorne of London said that many cases in children were of rheumatic origin, although without joint symptoms. Neurotic children often had a rheumatic inherited tendency.

Dr. Melland of Manchester thought malignant endocarditis had greatly altered in type in recent years and was therefore apt to be misleading. He also observed that unrecognized malaria might explain some cases.

Dr. William Hunter of London said the most important cases were infective. Some of these were specific fevers, as typhoid; the others were due to pyogenic organisms. The infection might originate in any part of the alimentary canal. An example was fever in gastric ulcer, for the ulcer was in reality an open wound.

Third Day—Friday, July 28.

Inhalations of Carbon Dioxide.—Dr. William Evart demonstrated an apparatus for use in the clinical employment of carbon dioxide by inhalation. He said it had been shown that the respiratory movements were affected by this gas in a way not formerly realized. It acted as a cardiac stimulant and indirectly as a sedative. By his apparatus the percentage of carbonic acid could be graduated, and not more than 4 per cent. should be used. A syphon of soda water discharged into the container, to which a tube with a mask for inhalation was attached, was a handy source always available. The papers read were:

Colon Indigestion.—Dr. T. Stacey Wilson of Birmingham, in this paper, held that many cases which pass as gastric were really colonic and might be diagnosed by palpation. The colon was hard and tender, probably from excessive muscular activity. Perhaps this was excited by microorganisms. Some general nervous instability was usually observable. Local pain in the colonic region with mental depression and various so-called dyspeptic symptoms were noted. Treatment was dietetic combined with intestinal antiseptics.

Recent Advances in Cardiac Therapeutics.—Dr. F. W. Price of London described some investigations on the action of digitalis and its congeners which had been made in the Mount Vernon Hospital for diseases of the chest. Out of thirty-six cases observed sixteen were of auricular fibrillation. Tincture of digitalis was administered in 20-minim doses three times daily until distinct reaction was obtained and then it was stopped. The speaker held this method to be better than beginning with small doses. Relapses were apt to occur in some of these cases, but not in those with normal cardiac rhythm.

Treatment of Morphinism.—Dr. Oscar Jennings of Paris read this paper. He insisted that the first thing was to convince the patient that he could certainly be restored if he would devote himself for sufficient time to carry out effectually the necessary treatment—hygienic, dietetic, and therapeutic. It was useless to try to deceive a patient with substitutes for his dose. To render him half comatose with bromides was futile. Dr. Jennings did not believe that any benefit resulted from large doses of hyoscine. The chief aim should be above everything to restore self-control. As a precaution against relapse exercise (cycling was excellent) and the use of the Turkish bath were recommended.

Mania Following Pneumonia.—Dr. J. W. Tyson of Folkestone read this paper. The condition, he said, usually occurred in distinctly neurotic patients under forty years of age who were also suffering from insomnia. The attack came on mostly after the crisis and was probably toxic. The prognosis was favorable. For the obstinate insomnia preceding the attack food was the best treatment.

Subcutaneous Emphysema.—Drs. Goodall and Kingsbury of London presented this communication. The causes were considered and a case related of a child twelve months old who had pneumonia and after about fourteen days the emphysema set in over the manubrium and the left side of the neck and face. The child died and at the autopsy there was found a congested state of both lower lobes and of the dorsal part of the upper ones. The liver was greatly enlarged. The author regarded this observation as confirmatory of Kieth's theory that expansion of the lower lobes and of the dorsal portion of the upper ones was effected by the action of the diaphragm.

The Sphygmooscillometer.—Dr. Halls Dally of London demonstrated this instrument, devised by Pachon,

which furnished information regarding both the systolic and the diastolic blood-pressure.

SECTION ON DISEASES OF CHILDREN.

Wednesday, July 26—First Day.

THE PRESIDENT, DR. OTTO J. KAUFFMANN OF BIRMINGHAM, IN THE CHAIR.

Diagnosis, Prognosis, and Treatment of Tuberculous Peritonitis.—Dr. H. D. ROLLESTON said that the various forms of abdominal tuberculosis should be separated as far as practicable in discussions on this subject as the prognosis varied considerably in the different groups of cases. Since most statistics failed to observe this differentiation their value was much impaired. Dealing first with the diagnosis of tuberculous peritonitis the chief difficultes were met with in early cases. For instance, the onset of a hernia might be the first sign of the disease. Again the development of a hydrocele with thickening of the spermatic cord might be the earliest symptom. In another group acute intestinal obstruction might develop in the absence of any definite signs of tuberculous peritonitis and yet might be due to that condition. In babies under one year of age the disease was rare and was very difficult to diagnose from other causes of abdominal distension. The onset of the disease was generally considered as usually insidious but in at least one-third of the cases it was sudden. In acute cases the diagnosis had to be made from acute appendicitis, pneumococcal peritonitis (general and localized), and from enteric fever. In the first of these it must be remembered that the tuberculous infection might predominate in the cecal region. When ascites was present the likelihood of the condition being one of tuberculous peritonitis was very much increased, other causes of ascites being rare in childhood. Cirrhosis of the liver, a very uncommon disease at this age, might simulate tuberculous peritonitis closely; jaundice and marked enlargement of the superficial abdominal veins favoring a diagnosis of hepatic cirrhosis. Tuberculin tests were of more value if negative than if positive, as they were of no avail in localizing the site of the tuberculous infection. Rectal examination might lead to the discovery of enlarged tuberculous glands. An examination of the ascitic fluid was of considerable help, an increase of lymphocytes being present in the tuberculous cases. In syphilitic cirrhosis of the liver of the Wassermann reaction of the blood and ascitic fluid would probably be positive. Abdominal malignant disease and polyorrhomeningitis or multiple serositis (itself sometimes tuberculous) might simulate the ascitic cases of tuberculous peritonitis. Where the fluid was encysted urachal or ovarian cysts might lead to a mistake in diagnosis but such were very rare, and ran an afebrile course. The prognosis in childhood, apart from infancy, was better than in adults, probably due to the frequency of hepatic cirrhosis and tuberculous salpingitis in the latter. Recovery was more common in the ascitic than in other types, but the case might change from an ascitic to an adhesive type and so lead to a good prognosis being falsified. Bad signs were persistent diarrhea or the presence of a fecal fistula. The more acute the onset the worse the outlook, although some observers did not agree with this statement. Pleurisy developing early made the prognosis bad; developing later it was less serious. Relapses were less frequent in children than in adults. Complications, particularly those associated with generalization of the infection, were common in children although not always easily recognizable clinically. Turning to the treatment of the condition the speaker thought general hygienic treatment, absolute rest, fresh air, and sunshine were most important. For drugs potassium iodide, guaiacol, iodoform and creosote were of value. The external application of mercurial ointment to the abdomen was of use. It had been suggested that this was merely due to the bandaging of the abdomen promoting local rest. In feeding, the avoidance of flatulence was of great importance. The results of tuberculin treatment were very conflicting at present. *X*-rays had probably no beneficial effect; if used in excess they might produce leucopenia. The subject of surgical treatment was still a very vexed one. Agreement might probably be claimed for the following propositions: (1) Operation was contraindicated in generalized or widespread infections, so commonly found in infants; (2) it was unnecessary in the adhesive form of the disease; (3) it was necessary in cases developing an abscess or obstruction. The chief difficulty was therefore on the subject of the ascitic cases, which it was acknowledged were the most easily cured by any means. An operation, by which was meant an open incision rather than paracentesis, had the advantage of enabling a localized area of infection to be removed. Statistics on the moot point of treatment were not satisfactory, as they were far too conflicting.

Professor G. A. WRIGHT of Manchester said that of the cases seen on the surgical side of the hospital the diagnostic points were usually distension, pain, and a local palpable mass to which might be added diarrhea or constipation, foul motions, wasting, and fever. Operation was contraindicated in cases showing an external fecal fistula. It was easier in the ascitic type, but the various forms of the disease could not be separated by any hard and fast lines. He found that above 50 per cent. of the cases lived to grow up; many died within two years. Tuberculous glands could be easily removed at the time of operation and this should be done. Summing up he thought that surgical treatment was of more value in relieving any secondary symptoms that might arise than in the actual cure of the disease.

Dr. CHARLES H. MELLAND of Manchester spoke as one who had been most favorably impressed formerly by the results of surgical treatment but was now equally gratified by the results of medical treatment, which he had latterly used almost exclusively.

Dr. WALTER JORDAN submitted that the differences between the opinions of physicians and surgeons depended to a large extent upon the differences in the types of cases which they saw. Where a surgeon worked with a physician who had all his cases operated on the results of surgery appeared to be brilliant, but where a physician sent only late and unfavorable cases to the surgeon the results of operative treatment must appear very poor. In this way discrepancies were caused in statistics. Again surgeons appeared to find ascitic cases very common, whereas in his opinion, speaking as a physician, they were far outnumbered by the other varieties.

Mr. MACADAM ECCLES advocated the application of a 1-1,000 solution of adrenalin to the peritoneum after an open operation. Other advantages of operative treatment were that the diagnosis was confirmed, foci of infection might be removed if present, strict rest and bandaging were enforced more successfully if an incision had been made and various symptoms might be relieved.

General Edema Following Gastroenteritis in Children.—Dr. W. E. HUME of Newcastle-on-Tyne read a paper based on the consideration of 13 cases. The symptoms of the group consisted of edema, coldness, cyanosis, and feeble circulation, the urine being free of albumin or casts. The coagulability of the blood was no different from that of control cases. In two fatal cases he had found fibrotic changes in the medulla of the suprarenal glands, while the kidneys were normal microscopically. Excluding renal disease the condition might be thought to be due to retention of salts in the blood but he had discarded this view, as he had found that increasing the

salt in the diet had led to no increase in the edema. He suggested that the changes in the suprarenals were etiological factors in the disease and this he thought to be confirmed by the good results he had obtained by the hypodermic administration of 5 minims of a 1-1,000 adrenalin solution twice daily.

Dr. H. D. Rolleston said that he had seen a diminution of the edema in these cases follow a deprivation of salt in the diet, although such might only be a coincidence. He pointed out that albuminuria might be present from renal edema in this group of cases.

Dr. Kauffmann suggested that the edema might be classified as neurovascular.

Dr. Hume replied that if due to suprarenal disease the edema would probably be of the type called neurovascular.

Infantilism Associated with Chronic Interstitial Nephritis.—Dr. Leonard G. Parsons of Birmingham described a case of this type. Physical growth was much impaired, the child being the height of one of 3 years of age although in reality 6½ years old. The mental condition could be best described as unduly childish. The patient had suffered from thirst and polyuria since birth. The urine contained a faint trace of albumin. Death occurred from bronchopneumonia. The kidneys showed marked interstitial changes, more severe in degree than those usually found in adults. The left ventricle of the heart was hypertrophied. The uterus was unduly ill developed. Such a condition of infantilism with renal disease might be regarded as due to loss of an internal secretion of the kidneys or might merely be due to the persistent excessive elimination, comparable to that due to severe and long-lasting diarrhea.

Dr. J. E. H. Sawyer of Birmingham did not think that all cases of contracted granular kidney in children showed a mental condition which could be called infantilism although many were physically much dwarfed.

Dr. H. D. Rolleston emphasized the importance of inherited syphilis in the causation of this form of renal disease in children. Dr. Reginald Miller instanced a case under his care exactly corresponding with Dr. Parsons' type, the child being shorter at the age of 9 years than his brother aged 4. He had given a course of thyroid for two months without any improvement in the child's growth.

Dr. Parsons in reply said that there were no signs of syphilis clinically or pathologically in the case reported and Dr. Morley Fletcher had recorded a case of a similar nature in which the Wassermann test had been negative. The thyroid gland in his own case had been found post mortem to be normal.

Thursday, July 27—Second Day.

The Diagnosis and Treatment of Chronic Pulmonary Affections of Children.—Dr. Samuel West of London stated that tuberculous processes in the lungs were usually acute in children. Such a condition as could be regarded as analogous to phthisis of adults was very rare in children. Even subacute tuberculous processes were rarely seen in children under the age of 5 years, although occasionally they were found even in infants. Similarly an hemoptysis of any severity was rare in young subjects. Chronic tuberculous pleurisy was rare in comparison with the frequency of chronic tuberculous peritonitis. Infected mediastinal glands were of course common, but the conditions originated by them in the lungs were more often acute than chronic. Such glands might give rise to recurrent attacks simulating those of asthma, or might set up pulmonary collapse or bronchiectasis. Skiagraphy was of great value in the diagnosis of enlarged mediastinal glands. Stridor and dyspnea of indefinite origin should suggest the possibility of a foreign body in the air passages. Bronchitis was usually acute in children. What was sometimes called chronic bronchitis in them was often merely a succession of acute attacks. Chronic bronchitis as seen in adults was rare in children. Genuine atrophic emphysema was uncommon and was probably due to nutritional changes and was not mechanically produced. No antecedent bronchitis was essential for its production. In the emphysema of children cyanosis was usually absent. Collapse of the lung was one of the most important pulmonary conditions in children. In infants it was produced by very slight obstruction owing to the weak state of the chest wall and the feeble character of the respiratory movements. Bronchitis was a common cause. The collapse was probably due to absorption of the air from the pulmonary alveoli, although it was difficult to understand how the nitrogen could be thus absorbed. Extensive collapse might cause considerable displacement of the heart. Bronchiectasis and bronchiolectasis in their chronic forms were associated with pulmonary fibrosis. Such conditions in children were probably always acquired and not congenital. In treatment, prevention was both easier and better than cure. Recovery from acute conditions tended to be more complete in children than in adults. In chronic cases treatment must be general and symptomatic. Disease of the mediastinal glands should not be overlooked, as by means of treatment in the early stages of this condition good results might be obtained.

Dr. J. E. H. Sawyer of Birmingham fully endorsed what Dr. West had said as to its rarity and computed, from an examination of his own figures that the proportion of phthisical children came to roughly 1 in 1,000.

Dr. Barty King of London regarded this figure as unduly low and suggested increasing it to 3 or 5 per thousand.

Dr. D. Stanley of Birmingham thought that perhaps 10 per cent. of children had phthisis.

Dr. N. C. Haring of Manchester regarded subacute phthisis as not uncommon in children although its course differed from that of adult life. He held that many such cases recovered temporarily but relapsed later, causing death at the age of 18 or 20 years. He had also found tubercle bacilli in the sputum of children regarded as suffering from bronchitis. The frequency of chronic pulmonary tuberculosis as reported by the medical inspectors of schools has varied enormously in different parts of the country, and the discussion showed well that the personal factor of the physician was a most important cause of these variations, while possibly confusion in nomenclature helped to exaggerate the differences in the results. On the whole the general opinion appeared to coincide with that of Dr. West, who had stated that phthisis was rare in children.

Dr. J. E. H. Sawyer alluded to those cases so commonly met with in children where there was a persistent cough in the absence of any abnormal physical signs in the chest. The nature of such cases was often very obscure, and he usually labeled them as "bronchial catarrh."

Dr. E. C. Myott of Newcastle attributed these cases to mouth-breathing and emphasized the possibilty of overlooking such a cause since many such children only adopted mouth-breathing after exertion and breathed normally during an ordinary medical examination.

Dr. Barty King of London emphasized the importance of the development of crepitations in a previously clear lung after a dose of tuberculin. Such he thought of great diagnostic value.

Dr. N. C. Haring of Manchester advised the routine use of mixed human and bovine tuberculin for subcutaneous injection.

The Value of the "Eustace Smith Bruit" in the Diagnosis of Enlarged Mediastinal Glands.—Dr. J. E. H. Sawyer of Birmingham from a careful consideration of his own cases concluded that the bruit was caused by the

stretching of the internal jugular vein against the transverse processes of the cervical vertebræ. He denied the diagnostic value of this sign.

Dr. S. West of London regarded the presence of this bruit as an aid to the diagnosis of enlarged mediastinal glands.

Nervous Influences in the Causation of Angiomata.—Mr. D. C. L. Fitzwilliam of London presented some interesting figures founded upon 700 cases observed in hospital practice. These included nevi and nevoid conditions (port wine stains and spider marks), circoid aneurysms and dilated venules being excluded. The sex incidence showed that 34 per cent. occurred in males and 65 per cent. in females. The preponderance of the latter was not to be accounted for by reasons concerned with the appearance of the patient in after-life as the sexes were represented in this proportion where the nevi were upon the unexposed parts of the body. These figures, therefore, probably represented the true sex incidence of angiomata. As to the age at which nevi made their appearance the speaker thought that, contrary to both lay and medical opinion, the vast majority were present at birth. In this connection two interesting facts were brought forward. First, nevi upon the face or hands were said almost invariably by the patients' mothers to have been present at birth. Secondly, of those which were said to have developed at a later date a very large number were stated to have appeared at the end of the second week, at such a date when the mother herself would wash the child for the first time. It was therefore highly probable that most of such nevi were in reality present at birth. The speaker's own figures showed that 83 per cent. were congenital. Of those appearing later "spider marks" were the most common. The distribution of the nevi were as follows: head and neck, 49 per cent.; trunk, 29 per cent.; limbs, 21 per cent. Many photographs were shown of nevi corresponding in area with the distribution of various superficial nerves. The nevus was usually darkest at the point where the nerve became superficial.

Disturbances Arising from Milk Feeding After the First Year.—Dr. Vogt of Strassburg stated that the chief of these disturbances was the exudative diathesis of Czerny, a tendency to various eruptions of the skin. Breast-feeding was no protection against this diathetic weakness. Rickets was to be attributed to milk-feeding, and the constipating effects of a milk diet were often overlooked.

Friday, July 28—Third Day.

The Epidemiology of Acute Poliomyelitis.—Dr. F. E. Batten of London said that the first known epidemic occurred in Sweden in 1881, and the first to be definitely investigated was that of Stockholm in 1886. In America small epidemics occurred from 1890 to 1900. Large outbreaks were reported in Boston and Massachusetts in 1906 and in more recent years further severe epidemics had occurred. In England epidemics occurred in 1905; a small one in Bristol in 1909, and a more extensive outbreak in various parts of the country in the following year. In Australia the first outbreak occurred in 1894. It was interesting to note that the maximum case-incidence was found in the months of March and April in Australia, corresponding to the summer months (July to September) in England. The speaker knew of cases which had occurred in South Africa although as yet unreported there. From the well-known Trästena school epidemic it appeared that the disease could be communicated not only by direct contact but also through the agency of a third person. The possibility of transmission through some carrier, such as an insect, was discussed; the evidence strongly suggested such an agent, but there was as yet no proof of the proposition. The speaker showed a map of London showing the distribution of the cases he had seen in 1904, and Dr. Leonard Parsons exhibited a similar map for 1909. In both maps it was seen that the cases were widely distributed over the London area. In conclusion the speaker emphasized the importance of recognizing the infective nature of the disease and urged that it should be made notifiable in the large towns. [Since this paper was delivered the disease has been made notifiable in London.—Ed.]

Spinal Anesthesia in Children.—Mr. H. Tyrrell Gray of London dealt with the value of this procedure in abdominal operations, an important section of the small group of cases in which it was of particular use. Speaking generally the advantage of spinal anesthesia lay in the fact that it was an adaptation of the "nerve-blocking" principle as opposed to the method of suspending the activity of the higher centers alone, as in general anesthesia. He deprecated the routine use of either procedure and emphasized the importance of adopting spinal or general anesthesia, or both, according to the needs of the particular case under treatment. The paramount factors in influencing the choice of spinal anesthesia were the age and condition of the patient. By this method the shock was very materially diminished and, since the younger the patient the more unstable the nervous system, spinal anesthesia was of particular value in dealing with children. In short, the younger the child the greater the indication for the use of this procedure. Similarly the less satisfactory the physique of the patient the greater the value of spinal anesthesia. The state of health of the patient must also be considered. Where an abdominal operation were necessary in a child suffering from pneumonia or some other disease, spinal anesthesia should be employed, or, again, where a great degree of toxemia was present the same procedure was indicated. In other words, there were many cases in which the administration of a general anesthetic materially increased the risk of the operation and in these spinal anesthesia might be employed with excellent results. In abdominal work spinal anesthesia led to increased manipulative ease and hence to more rapid operating and more satisfactory exploratory measures, while the risk of shock was much diminished. This method of producing anesthesia had been of particular value in acute abdominal conditions such as infective lesions of the peritoneum, intestinal obstruction (intussusception, etc.), and abdominal injuries.

Oxypathy and Uric Acid.—Professor Stoeltzner of Halle read a paper on this subject. He discussed the diatheses known as lithemia and arthritism, and their treatment with sodium citrate and sodium phosphate. In gout there was a retarded excretion of uric acid. Oxypathy was as common in children as gout was rare.

AMERICAN PEDIATRIC SOCIETY.

Twenty-third Annual Meeting, Held at Lake Mohonk, N. Y., May 31-June 1, 1911.

The President, Dr. Henry Dwight Chapin, in the Chair.

(Special Report to the Medical Record.)

(Concluded from page 453.)

The Preservation of Health in School Children.—Dr. Rowland G. Freeman of New York called attention to the great difference in the care bestowed upon infants and that given older children. The child attending school usually received attention only when he was sick and few of the protective measures applied to younger children were extended to him. On account of this neglect of children of school age fairly complete physical examinations of children beginning school life should be made. When such examinations were made it was surprising how many defects were found. The first year of school the

child should have but one hour in school and that should be interrupted by periods of rest and exercise. The duration of the school day should be gradually lengthened. At the age of ten years the child should not be in school more than four hours and should have no home studies. It was true of children, as of adults, that worry, not work, broke down their nervous systems. The student, whether ambitious or stupid, should not be pushed too hard. In the effort to eliminate the conveyance of contagious disease, the separation of the children and the ventilation of the school room played an important part. Children would do better in a room whose temperature was 50° or 60° F. and properly ventilated. The schools were the chief means of conveying contagious diseases. The speaker illustrated this statement by charts. The nose and throat affections were the diseases most frequently communicated. Every child with a cold should be excluded from school. Every child exposed to a child taken sick at school during the period when the disease was apt to be developed should also be excluded from the school. The school authorities should be held responsible for epidemics. The speaker said that the following were essentials for the preservation of good health among school children: Short school hours; frequent recesses; open or well-ventilated and cool school rooms; roof playgrounds. There should be individual study for backward children. A medical supervisor should have control of the preservation of the health of school children.

Dr. Graham of Philadelphia said he would like Dr. Freeman to include in his paper a reduction in the number of studies in the public schools. Girls of ten or twelve had seven or eight set studies, were in school from nine in the morning to four in the afternoon in Philadelphia, and then had to prepare lessons at home. Dr. Graham thought that tests or examinations should be done away with. When children were subjected to a test every two or three weeks their nervous systems were kept in a fever of excitement.

Dr. Blackader of Montreal said that he wished to emphasize the points Dr. Graham had made. He thought it would be wise for this society to come to some definite expression of opinion on the subject and to have it published in the papers.

Dr. Charles Herrman of New York, discussing the question of preventing the spread of contagious diseases in schools, said that many things which were possible in public schools could not be carried out in private schools. The value of the work of medical school inspection varied greatly in different cities; in New York City the system was very complete. The results obtained depended very much on the individuality of the inspector and the amount of cooperation on the part of the principal and teachers; the latter was indispensable. The possibility of preventing the spread of different contagious diseases differed greatly. While it was practically impossible to prevent the spread of measles, he believed that in New York City, at least, the public schools could not be held responsible for the spread of scarlet fever.

Dr. Morse of Boston reminded them that in considering the breaking down of young girls in school they should not forget that it was not the school work alone; they should remember the dancing lesson, the music lesson, and the French lesson.

Dr. Kerley of New York thought they should also take into consideration that fact that in cities like New York when the children were not in school they were on the street, and schools for play with paid instructors should be provided, which should be open not only during the week but on Saturdays and holidays.

Dr. Samuel Adams of Washington agreed with Dr. Morse that more blame should be placed upon the parents than upon the schools. Sufficient calories should be provided for the child to work upon, and then they would get better work and less breakdown. Dr. Adams spoke strongly against the parents permitting children to go to school without a good breakfast. It was not overwork so much as improper feeding that accounted for these troubles. The dancing school and parties were also a means of transmitting contagious diseases.

Dr. Jacobi said that if many children went to school without breakfast the question was a social one. There were 600,000 children in the public schools of New York and many of them had no breakfast or a very poor one. The same thing applied to the teachers. There were a great many of these girls, 18, 20, and 22, teachers, who were starved. In the interest of the country these children should be properly fed. If Dr. Freeman referred to the children of the better classes he was right, but he had failed to cover the case entirely for the majority of the 600,000 children with whom they had to deal. Theoretically they were pretty well off in regard to school inspection. However, a great deal of imperfect work was done. The Health Department should have an appropriation that would enable it to do its work properly.

Dr. Chapin of New York said that this matter of breakfast had come up several years ago and he had been one of those appointed to investigate conditions. The result was that they had found that no such dire condition existed as had been pictured. If children went to school without breakfast it was because sufficient care had not been exercised by the parents. It happened oftener from ignorance than from poverty. Not so many went to school without breakfast as was supposed.

Dr. Freeman said that it might be of interest to state in this connection that a great many of the public school children in New York were now being provided with cheap lunches.

The Surgical Management of Acute Suppuration of the Lymph Glands in Infancy.—Dr. Thomas S. Southworth of New York presented this communication. He said that no surgical dictum had a broader application than that which predicated that where pus existed it must be evacuated. It was, however, worth considering whether this surgical canon had not been interpreted too broadly in the extent of its application to localized collections of pus in situations that involved little or none of the danger associated with the rapidly spreading necrotic types. In acute suppurative processes in the lymphatic glands in infancy they were dealing with suppuration beginning within the capsule; this rarely extended outside except in the search of an exit along some line of easy resistance. This latter tendency was a conservative process. When the lymphatic gland found the task too great suppuration ensued within the gland. Upon extension of the suppuration toward the periphery of the gland and the destruction of its parenchyma, a second line of defensive inflammation was established about the capsule which limited the destructive process except at the point which might be chosen for the spontaneous evacuation of the pus. At this stage they had a periadenitis; the gland was less movable, and the presence of pus was practically certain. Their procedure, therefore, in incising such an abscess was not to check the destructive process by heroic measures, but to give the requisite aid to complete a conservative process. Incision of the gland that had only partially broken down into pus delayed rather than hastened the period of healing. There were contraindications to the advisability of waiting until there was distinct fluctuation before undertaking surgical relief. The only indication for a large incision in acute abscesses was to secure drainage; such free incisions in acute abscesses in infancy were not only unnecessary from a surgical standpoint, but were unnecessarily mutilating. The smallest incision that would allow gentle expression of the pus and the smallest drain-

age tube that would permit of the continuous escape of the seropurulent discharge from the cavity were all that were required. The incision should not exceed five-sixteenths of an inch. The dressings were changed at the end of forty-eight hours and by that time the walls of the abscess cavity had contracted and there were evidences of granulation. The tube could then be dispensed with and subsequently a dressing of ichthyol ointment, 10 to 20 per cent., could be employed. This was continued until cicatrization was complete.

Which Is Preferable in Colon Irrigations—the Long or the Short Tube? A Comparison Based on Two Hundred Irrigations.—Dr. Henry T. Machell of Toronto said that he had felt for several years that in giving rectal irrigations to children the use of the small short rectal nozzle was preferable to the rubber catheter or the flexible rectal tube. In a number of instances he had seen the tip of the catheter appear when he had flattered himself that it was 10 or 12 inches up the colon. Another objection to the catheter was that it must be introduced by a number of pushes or shoves; the more of these the more uncomfortable the sensation, especially when it was practised for some inflammatory condition of the rectum or colon. The possibility of traumatism should also be considered. The speaker presented records of 200 cases of irrigation done during the winter of 1909. He thought that they showed that for the amount injected the short nozzle had the advantage whether the cases were acute or chronic, or whether the age and weight were considered or not. The fluid was retained for a longer time when the short nozzle was used. The amount permanently retained was larger when the short nozzle was used. That the fluid could be made to go up as far as the cecum with the use of the short nozzle could be readily proven by the stethoscope; that the long tube ever got past the cecum was not so easily proven.

Dr. Jennings of Detroit said that Dr. Yates had made some interesting investigations along this line. He had shown that it was practically impossible to introduce a long tube into the colon. With the *x*-ray he had shown that the tube could not be introduced above the sigmoid; it simply folded over and remained in the lower part of the bowel.

Dr. Jacobi of New York said that the paper and remarks of Dr. Jennings had covered the case entirely, but they might have told why it was impossible to put the long tube into the colon. It was possible to bring the tube into the colon with adults, but not with children. In children they simply lifted the sigmoid flexure. Dr. Jacobi had not attempted to use the long tube in babies for thirty years. In order to facilitate the operation in giving an irrigation it was better to raise the hips of the baby and to have it lie a little toward the left, rather than toward the right, and then the fluid would run in spontaneously.

Dr. Henry Dwight Chapin of New York thought that this paper and discussion put on record would do a great deal of good and add to the comfort of many babies. He had taught this for many years, although he had not performed the experiments that Dr. Machell had.

Dr. Machell of Toronto said, in closing, that he had gotten his idea at home when one of his own babies had ileocolitis and he had ample opportunity to do colon irrigations. He had concluded that the writers who advocated the long tube had not tried to use one themselves in their own homes.

A New Method of Calculating Milk Percentages.—Dr. L. Emmett Holt of New York presented formulæ obtained from milk containing different percentages of fat and an infant feeding card which he used in the Department of Diseases of Children, College of Physicians and Surgeons, reference to which would easily enable one to make out the formula required. Dr. Holt also gave statistics showing the good results obtained with these formulæ.

Dr. Blackader of Montreal asked Dr. Holt just what gain he got in the average case.

Dr. Holt replied that 61 children gained on the average one pound and ten ounces during an average stay of forty-seven days.

Dr. Churchill asked whether the one pound ten ounces was the gain above the weight when admitted or above the lowest point while in the hospital.

Dr. Holt replied that it was the weight above the lowest point during their stay in the hospital.

Dr. Churchill asked why they did not use partial breast feeding; whether it was because they did not have wet nurses. In his service they kept several nurses for this purpose and it was astonishing what an amount of milk they could furnish. One gave five quarts daily. They pumped off the milk and did not permit the nurse to incur the risk of infection.

Dr. John Ruhrah asked Dr. Holt whether he had noticed any difference with the children that came in with gastrointestinal disturbance. Did they do better than the others?

Dr. R. G. Freeman thought that the only disadvantage was that they would have to carry the booklet around with them. Most of them were getting down to simpler dilutions and not depending upon such accurate percentages. It was better for the general practitioner and for the medical student.

Dr. Henry Dwight Chapin of New York thought it was wise for institutions to compare results, but it should be remembered that the personal equation counted for much and what one would call good another would call bad. They must distinguish the cases in which there was gastrointestinal irritation and those of pure marasmus. The latter would all die in the hospital.

Dr. Koplik of New York said that he was glad that Dr. Holt had shown that infants did gain in American hospitals. There was an impression abroad that they did not gain in hospitals here.

Dr. Knox of Baltimore said that he was glad that Dr. Holt had told them that he began his cases of malnutrition with mixtures derived from whole milk. Except in very young babies they did not use the cream mixtures.

Dr. Holt said the reason they did not give more breast feeding was because they did not have the wet nurses. Only 27 of the cases got wet nursing, hence the figures did not show that the majority of the gain was due to wet nursing. Two-thirds of those classed as improved made their gain on artificial feeding. The gastric cases were comparatively easy to control, but the intestinal cases did not yield to treatment so readily, and those were the ones they lost. The caloric method had not helped them much; he had calculated it more as a matter of amusement than anything else. The percentage method furnished the best indication of exactly what they were giving a baby.

Dr. Chapin of New York said he was glad to hear Dr. Holt speak as he had about the caloric method. Personally, the more he used it the less he thought of it.

Dr. Morse of Boston thought they should use the percentage method as a basis for feeding, but they should use their calories as a check to know if they were giving enough food in calories or not.

Dr. Cowie of Ann Arbor agreed with the statement just made by Dr. Morse.

Dr. J. P. Crozer Griffith of Philadelphia said that he should like to maintain the position taken by Dr. Holt and Dr. Chapin. He thought the caloric method was a useful check; but what were sufficient calories? The caloric need of one child differed from that of another.

Dr. Kerley of New York said that he had been about to say just what Dr. Griffith had said. The activities of the child determined the caloric requirements.

The Use of Malt Sugar and High Percentages of Casein in Infant Feeding.—Dr. John Lovett Morse of Boston read this paper. He said that Finkelstein and Meyer believed that the diarrheal diseases of infancy originated in functional weakness of the intestines and that this weakness was kept up by fermentation. If this was the case the first step in the treatment was to stop the fermentation. This had been done in the past by cutting down the amount of food and giving a food not susceptible to fermentation. Fat, sugar, and proteid were all susceptible to fermentation. Meyer and Finkelstein concluded that casein had an antifermentative action. Milk sugar must, by exclusion, be the cause of fermentation. The speaker reviewed the process of reasoning by which they arrived at their conclusions and described the development of the food which they used to combat these indications. Dr. Morse expressed himself as not prepared to accept the statement of these men regarding the treatment in all disturbances of nutrition in infants which were accompanied by diarrhea. It seemed to him that they had made out a strong argument against sugar as an etiological factor in fermentation, and that the treatment of fermentative conditions by a food very low in sugar and high in proteids was, therefore, rational. The substitution of dextrin-maltose mixtures for lactose also seemed rational. It seemed to him that they might take advantage of what was best in this method of treatment, and at the same time avoid the disadvantages of a routine food and the superfluous buttermilk by applying them in the modification of the milk by the percentage method. By the use of cream containing a high percentage of fat it was possible to reduce the amount of unprecipitated casein to a very low percentage. The precipitated casein was prepared according to the method of Finkelstein and Meyer, the casein from one quart of milk being made into an emulsion with sufficient water added to make one pint. This method of treatment was tried only in cases of intestinal disturbance associated with indications of fermentation and in which there was none or little vomiting. Only sixteen cases were available. Eight of these had to be excluded. A detailed account of these cases was presented and the speaker felt certain that this method of treatment of intestinal disturbances associated with fermentation in infancy by the withdrawal of lactose and by raising the percentage of casein, followed by the addition of dextrin-maltose, was a valuable one.

Dr. Koplik said that in justice to Finkelstein they should, if they were going to talk about Finkelstein's methods, follow out exactly his methods. As soon as they began to modify the method it was no longer his. Dr. Koplik agreed that it was one food to fit all cases and was too much of a routine method. The material that they worked with was not so completely controlled as that of Dr. Finkelstein. There were a considerable number of milder cases in with the severer ones and the statistics were drawn from these. Another point that Finkelstein made was that he did not starve the babies too long and he maintained that this food could be given when the baby was very sick. Finkelstein said that with older children he could get the same results by other methods.

Dr. Jacobi pointed out that the method had several advantages, little fat, little milk sugar, and more of other carbohydrates. Some of them had followed this method for fifty years. The great principle in the treatment was little fat, little milk sugar, and more of other carbohydrates.

Dr. R. G. Freeman of New York said that the children would not gain much on Finkelstein's method unless more sugar or fat was added.

Dr. Holt thought they could hardly call it a low fat food as it gave 3 per cent. fat.

Dr. Morse of Boston said he hoped that he had made it clear that he was not using Finkelstein's method, but had merely adopted some of his suggestions and applied them.

Pyloric Stenosis in Older Children, with a Report of a Case of Pyloric Spasm, Ending Fatally in a Boy Six and One-Half Years Old.—Dr. Edwin E. Graham of Philadelphia presented this communication and said that it was his intention to consider stenosis of the pylorus in children who had passed the period of infancy. The etiology had been attributed to some disturbance of gastric secretion and consequently gastric indigestion and hyperplasia. The classical symptoms were vomiting, constipation, loss of weight, scanty urine, and a peristaltic wave; sometimes a tumor was found at the site of the pylorus. The treatment consisted in proper feeding, washing out the stomach, the administration of opiates, the application of poultices to the epigastrium, saline enemata, nutritive enemata, etc., and, if indicated, operation. The author thought the following conclusions regarding hypertrophic pyloric stenosis seemed justifiable: (1) That pyloric stenosis was present in children and young adults longer than was supposed. (2) The age at which it manifested itself depended upon the degree of the stenosis present. (3) Pyloric stenosis might be latent for years. (4) It had been found that during childhood and young adult life the early recognition by the physician was very important from the standpoint of early medical or, if necessary, surgical treatment. (5) The entire disappearance of all the classical symptoms of congenital pyloric stenosis and the apparent health of the infant during its subsequent early childhood being restored, no gastric dilatations might develop later in life. The speaker gave the history of a case of pyloric stenosis in a boy six years of age, whose general health during infancy and childhood had been first class until a few months before death. During life he presented the typical picture of pyloric spasm. No disease of the pylorus, stomach, or other portions of the intestinal tract was found postmortem. The case was not connected with any organic disease of the stomach or with any changes in the normal gastric secretion. Pain was absent. Vomiting was one of the prominent symptoms. The loss in weight was extremely rapid. The loss of weight and the violent and persistent vomiting made the case differ from those described by most of the writers on this subject. In this patient enucleation of an eye was necessitated because of an accident; sarcoma subsequently developed. The case seemed to belong to a group of cases of so-called reflex vomiting associated primarily with disease of the eye, and later aggravated by a sarcomatous metastasis in the liver. The speaker thought that a clear understanding of this condition in infants would help them in the recognition and study of the condition in older children.

A Discussion of Mikulicz's Disease, with a Report of a Case of Lymphatic Leucemia in a Child with Marked Enlargement of the Salivary Glands.—Dr. Wilder Tileston of New Haven, Conn., read this paper, in which he stated that in the year 1891 Mikulicz described a new disease characterized by chronic bilateral painful enlargement of the lacrymal and salivary glands. In the case which formed the basis of his report the blood was normal and there was no enlargement of the lymphatic nodes or spleen. The histological picture resembled that of a lymphoma. After a complete extirpation there was no recurrence. Since that time cases had been reported in which the pseudoleucemia was accompanied by a similar enlargement of the lacrymal and salivary glands. The speaker reported a case of lymphatic leucemia of a leucemic type in a child two years of age; there were large tumors in both of the parotids, and both submaxillary glands, the lacrymal gland not being involved. At autopsy it was found that there could be but little doubt but that this case could be classified as above, that was to say, without an increase of the leucocytic count. The case fitted in

with the Mikulicz syndrome. The histological appearances of the salivary glands were identical with what had been described in many cases of Mikulicz's disease without involvement of the blood or lymphatic system. A search through the literature showed that the association of leucemia with the Mikulicz syndrome was extremely rare. The speaker offered the following conclusions: (1) The term Mikulicz disease should be reserved for those cases of chronic bilateral enlargement of the salivary and lacrymal glands in which the pseudoleucemia and leucemia could be excluded. (2) The cases occurring in the last-named disease should be classified as pseudoleucemia or leucemia with the Mikulicz syndrome. (3) The cause of Mikulicz's disease was probably some infectious agent in the widest sense of the word. It was likely that a number of different organisms might cause the symptoms of the disease.

AMERICAN ORTHOPEDIC ASSOCIATION.

Twenty-fifth Annual Meeting, Held in Cincinnati, May 15, 16 and 17, 1911.

(Concluded from page 352.)

Further Experience with Volkmann's Ischemic Paralysis by the Method of Robert Jones.—Dr. Reginald H. Sayre of New York City stated that Volkmann's ischemic paralysis was the result of a myositis set up by obstruction of the supply of oxygen by pressure by either bandages or splints, and sometimes by position and pressure of bone fragments. Shortening of the affected muscles resulted, the muscles of the forearm being those usually affected, those of the hand occassionally. Massage was too intermittent to produce good results. Shortening of the contracted muscles produced results when massage failed, as it was constant, instead of intermittent. In some cases bone growth at a faster rate than muscle growth might cause a recurrence of the deformity in a way analogous to the recurrence of equinus in cases of paralysis, and a second stretching might then be necessary.

Dr. Leonard W. Ely asked whether there had ever been any evidence adduced to show that the cause of this paralysis was a tight band. If the paralysis was caused by a tight dressing he did not see why one did not get constriction in the parts distant from the dressing.

Dr. Alexander R. Colvin had seen in the last year two cases of severe ischemic paralysis following fracture, though no dressing had been used at any time.

Dr. Stern had recently seen what appeared to him to be a typical case due to the misuse of a bandage, which had been applied tightly a little above the elbow and kept on twenty-four hours.

Dr. Davis thought that perhaps in the majority of these cases the cause was not so much the muscular as the nervous element. In the case of claw-hand exhibited he thought that the ulnar nerve was affected. In many cases of ischemic paralysis the proper treatment would be to clear the nerves, as well as isolate the muscles.

Dr. Sayre, closing, said that he had drawn attention to the fact that all these causes might act to produce ischemic paralysis. The experiences of different observers were somewhat at variance, as well as the results of animal experimentation. He also stated that these patients did have symptoms of constriction, but that they were usually disregarded. The reason that ischemic paralysis was so much more freqnent in children was that the adults removed the dressing, but the children could not do so. Anything that cut off the blood-supply might produce it.

Exercise Treatment of Paralysis.—Dr. C. H. Bucholz of Boston stated that exercise held a prominent place in the treatment of paralyses. Its main indications were the stimulation of the affected nerves, the education of new nerve tracks, the training of muscles, the prevention and cure of articular complications, the stimulation of the development of the growing bones, and the care for the general conditions of body and mind. The relation of exercise to tendon transplantation and postoperative treatment was considered, and the necessity of saving the muscular tissue. Particular attention should be paid to the position, the angle of the movement, and the support. The stretching exercises which were indicated in cases of hemiplegia and similar types of paralysis needed a fine and subtle technique. Overexertion, both local and general, was to be avoided. The experience of the last two years had offered us much encouragement to pursue these exercises and attempt to improve them, and had given results that he had been unable to obtain in any other way. Dr. Bradford said that these cases were all so hopeless unless something was done that every means possible should be taken, and one of the means was this, which has caused improvement even months and months after the onset of the paralysis.

Dr. Osgood also bore witness to the value of this work of Dr. Bucholz, who saw these cases in a clinical way, many of them being patients that he and Dr. Bradford had felt quite discouraged about. The results of this treatment, though slow, had in the end been the most brilliant of any that they had had anything to do with. The work, however, involves a patience and a detail that are enormous.

Dr. Truslow stated that if there was deformity present it should be corrected by mechanical means before this treatment was instituted.

Dr. Cone referred to a case of paralysis of the throat. The patient was unable to use the involuntary muscles in swallowing, and had to be fed through a stomach-tube. After an education of some months she was able to use the voluntary muscles in place of the involuntary, and now she has practically a new throat.

Dr. Bucholz, closing, thought that overexertion of the patient was allowed too frequently by even well-trained men, and some very bad results had been caused by it.

X-Ray Studies of Arthritis Deformans.—Dr. George R. Elliott, of New York City, had selected these cases from a large number of cases of chronic arthritis. The *x*-rays showed new bone-formation about the joint and distant from the joint, and also along the shafts of the long bones. They also showed holes cut out of the bones, general atrophy of the bone, ankylosis, subluxations, dislocations, transparent areas, areas of density of bone, fusion of bone, etc.

Dr. Ely thought it a mistake to regard these as cases of bone disease. In all these lesions the bone played merely a passive part, forming a mere frame-work to the changes going on in the marrow. Some infection was at the bottom of them all.

Dr. Goldthwait said that the joint manifestations did not represent the primary disease, but were manifestations of something else wrong with the system. One should find the cause first and attend to the joints after that had been removed.

Dr. Elliott, closing, said that he regarded the trouble in the joints as purely secondary and that chronic arthritis was undoubtedly in a fair way of being cleared up from an etiological standpoint.

Treatment of Scoliosis (Illustrated by Stereopticon).—Dr. Edward H. Bradford of Boston said that in all cases it was essential that careful records should be made not only of the curves and contour of the back but also of the spinal flexibility. Spinal curves resulted from the inability of the spinal column to carry the superimposed load. They varied greatly in degree according to the varying strength of the back body and leg muscles and also according to the strength of the bone tissues of the vertebræ, and in treatment it was important that the right measures should be used at the right time and in weak backs only the weakened

muscles should be strengthened. Class work was to be avoided and each case was to be treated individually. In curved backs with a commencing localized stiffness, flexibility exercises which stretched only the stiffened regions should be employed and not those which made the flexible parts more flexible and left the stiffened parts unaltered. In twisted backs the constant use of the correcting force was needed until the bones were strong enough not to be altered in shape and structure.

Results of Treatment of Scoliosis at the Boston Children's Hospital.—This paper, which included a lantern demonstration, was written by Drs. Robert W. Lovett and J. W. Sever of Boston and read by Dr. Lovett, who gave a presentation of the results of treatment in lateral curvature by means of photographs showing postural or functional curvature and its treatment by gymnastics, as well as structural or organic curvature and the treatment of moderate and severe cases by forcible jackets either permanently worn or worn for a short time and followed by removable jackets and gymnastics. He stated that the problem of severe lateral curvature was a bone problem and not a muscle problem. The treatment advocated was addressed to the reshaping of bone. A demonstration by lantern slides of methods and cases before and after treatment was given.

Dr. Truslow thought that there were cases of functional scoliosis that needed supportive treatment as well as exercise. He preferred to change the jacket every time there was a change in the condition of the patient and to try to get as much correction in every phase of the deformity as possible. Accurate measurements were necessary to give an accurate idea of the changes.

Dr. Bradford, closing, said that he considered photographs as notes, but not as true records. He had been impressed by the results accomplished by the constant pressure, night and day, of a light apparatus. In private practice one could not apply plaster constantly for three or four years, and some cases needed it as long as that.

What Is to Be the Attitude of the Orthopedic Surgeon with Regard to the Child with Congenital Ptosis of the Abdominal Viscera?—Dr. Joel E. Goldthwait of Boston said that the type of child he wished to consider was the one who stood in an incorrect attitude. Such children had the arrangement of the visceral supports found in quadrupeds. One person in every five was born before the embryological changes that differentiate the human species from the quadruped had taken place, as these occurred in the latter part of embryonic life. They had bilious attacks and difficulty in their nutrition and later had neurasthenia, with round shoulders and various other deformities. If one could give a little support to the viscera the children would stand better. The force of gravity should be used in such a way that instead of its constantly making the position worse it pulled the parts to where they should be.

Dr. Compton Riely of Baltimore stated that if the pelvis was tilted forward it was a mechanical impossibility to get the ribs separated and the lungs expanded. In the treatment one should make an effort to have the patient tilt the pelvis backward. This had to be done largely by means of exercise, especially of the leg muscles, doing away with heels on shoes, if possible.

Dr. H. L. Taylor reported that it had occurred to him that the old knee-chest posture of gynecology might be a good one to have the patients assume. He had seen plenty of neurasthenics that had none of these faults in posture, and numbers of persons who had them were not neurasthenics and had no arthritis deformans.

Dr. John Dunlop of Washington, D. C., had found the stomach of such patients in the knee-chest position to be five or six inches higher than when they were trying to stand.

Dr. Goldthwait, in closing, stated that a good exercise was to have the patient crawl off the edge of the bed, letting his head hang to the floor, keeping this attitude long enough for the muscles to tire and the organs to sag back. The knee-chest position had the disadvantage of causing an additional sacroiliac strain.

The Anterior Heel: A Further Contribution to the Question of Balance.—Dr. Ansel G. Cook of Hartford said that the anterior heel was a triangular prism-shaped strip of leather about two inches in width and from 2-16 to 5-16 of an inch in thickness at its center. This strip of leather was placed obliquely between the inner and outer soles, and lay just behind the anterior arch or ridge formed by the heads of the metatarsal bones. The shoe was provided with a heavy steel shank which was supported behind by a low, broad heel, and in front by the anterior heel. The anterior heel, when studied in connection with the steel shank and the posterior heel, was an important element in the balance of the shoe. The anterior heel afforded instantaneous and efficient relief from all troubles of the anterior part of the foot, whether considered singly or collectively. The common cause of all these troubles was undue pressure; and the anterior heel, by removing this pressure, removed the cause and placed the injured parts in a position where recovery was possible. Shoes and instep supports made in this manner and worn indefinitely would in no way injure normal feet.

Pathological and Symptomatic Weight-Bearing: A Consideration of the Prevention and Cure of Foot-Strain.—Dr. Robert B. Osgood of Boston said that included under the name of foot-strain were those conditions in which faulty weight-bearing affected the anatomical structures of the foot that were designed to protect and maintain its arches and regulate its circulation. The tarsus and the first metatarsal with its phalanges were the portions of the foot actively concerned in progression. The muscular anatomy was the most important factor in mnintaining proper weight-bearing lines. The most common predisposing cause of foot-strain was abnormal muscle balance; and the most common exciting cause, the modern ready-made shoes. An important point in reaching the diagnosis was the examination of the patient's well-worn shoes. If the muscle balance was nearly or quite normal, the symptoms being due to bad footwear, various flexible-shank shoes might be used. In other cases rest in some form was the most rational immediate treatment.

Dr. Davis felt that a flexible-shank shoe had ordinarily no advantage over a stiff-shank shoe. The latter was more stable and less liable to distortion.

Dr. Cook asked whether Dr. Osgood referred to flexible shank shoes, with or without heels.

Dr. Ryerson thought that unless the tibia were firmly fixed, no estimation of the power of the abductors and the adductors of the foot could be made.

Dr. Osgood, in closing, said that it would be better if one could get rid of shoes altogether, because almost no shoe was absolutely nature-shaped. Flexible shoes allowed freer foot action and overcame to a certain extent the disadvantages of shoes in general. What he had said referred to the flexible-shank shoe without a heel. It did not seem as necessary as one would think to rule out the hamstring muscles in calculating the power of the foot-muscles. The point was to measure the pull in one direction and in the other under the same conditions.

Further Observations on the Operative Plan for the Correction of Relapsed and Untreated Cases of Equino-Varus.—Dr. Michael Hoke of Atlanta described the anatomical and mechanical details of several very bad cases that were corrected. The plan consisted in remodeling the metatarsus, the tarsus and the ankle so that the skeleton would be balanced, there being thereafter no occasion for disturbance of muscular balance. The meta-

tarsal operation consisted in osteotomies of the shafts of the metatarsal bones, correcting their inward inclination. The tarsal operation consisted in remodeling the three cuneiform bones, the cuboid and the astragalus so that these bones would be as near their normal shapes as possible. In the deformity, the external malleolus was twisted backwards so that it held the os calcis in a position of outward rotation and prevented the body of the astragalus from gliding backwards when dorsal flexion was attempted. The plan of the ankle operation was to bring the external malleolus forward, widening in this way the ankle joint, thus permitting the body of the astragalus to be received between the two malleoli.

Dr. Cone felt sure that almost any child's club-foot could be remodeled properly without cutting. If, however, cutting should be necessary, the Phelps operation would be satisfactory.

Dr. Riely asked whether this operation allowed of more elasticity than the other operations and whether it ever caused metatarsalgia.

Dr. Davis thought that a foot corrected by Dr. Hoke's method would be corrected for good, as an ankylosis would practically fix the foot in the corrected position.

Dr. Hoke, in closing, said that he did not see any more harm in doing osteotomy of the tarsus than in doing a linear osteotomy for bowlegs. There was no ankylosis of the foot after these operations, which were followed by the development of the foot. Regarding the Phelps operation, he did not see why smashing everything in the foot was a rational procedure to correct bone deformity.

Psoas Abscess from Retroperitoneal Lymph-Glands.—Dr. Mark H. Rogers of Boston gave a report of seven cases of psoas abscess from suppuration of the lumbar retroperitoneal lymph-glands without spinal involvement. The anatomy of the abdominal lymph-glands was discussed to show the probable etiology of these cases, and to show that this condition was entirely separate from tabes mesenterica, a distinction that was not well recognized in the various text-books.

Dr. Cone stated that a knowledge of the pathology and anatomy in these cases would help orthopedic surgeons and, through them, the general surgeon in working out the proper treatment of these difficult so-called retroperitoneal abscesses, which were often due to infection of the glands.

Dr. E. G. Brackett of Boston thought that these cases emphasized the need of orthopedic surgery; for they were apt to go unrecognized, except through that medium.

Dr. Ely hoped that Dr. Rogers would repeat the diagnostic points in closing the discussion.

Dr. Rogers, closing, said that the conditions liable to come up in making the diagnosis were appendix and kidney abscess, hip and spine disease and pelvic abscess. In most of these cases a lesion of the spine was suspected. It was hard in a number of cases to get the general surgeon to look for a psoas abscess first; he usually wanted to open the abdomen.

Orthopedic Treatment of Fractures of the Humerus.—Dr. Frank E. Peckham of Providence said that the general surgeon of to-day was intensely interested in abdominal surgery and not in fractures. Fractures were mechanical problems, and hence of very great interest to the orthopedic surgeon. The humerus was selected simply to show illustrative cases. Any other bone would have answered as well. The *x*-ray was valuable in showing the condition before reduction, and of double importance after attempted reduction in verifying the condition. Mobilization was important in hastening the restoration of function. The operative treatment should be the last resort, as the skill and mechanical ability of the orthopedic surgeon should overcome most difficulties, thus rendering the open operation seldom necessary.

Dr. B. E. McKenzie of Toronto wanted to know whether Dr. Peckham, in making the motions of extension, abduction and circumduction for fractures of the surgical neck, did so with the intention of making motion at the point of fracture or to keep the fracture in place.

Dr. Ely remarked that fractures about the head of the humerus sometimes occurred with dislocations of the shoulder joint. They were usually reduced and put up in the adducted position, and one got a pronounced degree of Dupre's bursitis. If the joint was put up in the extreme abducted position and kept that way for a month, the greater tuberosity, which had been broken off and slipped up, giving rise to this lesion, would go down into its place.

Dr. Brackett said that in many cases the time came when one could employ surgical procedure with safety, and possibly a little more surety than with the simpler method. The use of bone-plates and hardware prevented having to keep the patients in bed for two or three weeks or to confine the extremities, giving security that the fracture would not slip during the treatment.

Dr. H. L. Taylor stated that in some cases it was necessary to put in plates, but that the surgeon should not think first of using these. It was rational to lock the bones by serrations and indentations and to keep them in position by means of posture.

A Removable Plaster Corset for Structural Scoliosis.—Dr. David Silver of Pittsburg considered that the advantages of the removable plaster corset were its cleanliness and its freedom from pressure, allowing the opportunity for frequent inspection and permitting the use of corrective exercise (in recumbency) either during the entire period of treatment or in the later stages. The neck portion came well up on the base of the neck. Instead of carrying the plaster up to the neck it might be stopped at the shoulders and a metal neck and shoulder attachment used.

Dr. Truslow stated that the neckpiece was extremely uncomfortable and that patients did not like to wear it. He preferred a corset made of celluloid, with a single opening in front. It could be reinforced with strips of metal.

Dr. Stern said that celluloid was objected to by many on account of the danger of fire, but that if crystals of the chloride or iron were added to the celluloid for the middle layer of the jacket the material would be be made practically non-inflammable.

Dr. Silver, in closing, said that he did not think the neck-piece uncomfortable, especially the metal one, because it could be bent until it fitted comfortably.

The Operative Approaches to the Hip-Joint.—Dr. E. G. Brackett of Boston said that it was impossible to fully expose the hip-joint by any one incision. It needed to be approached by the different avenues, according to the part of the joint to be attacked. The hip-joint differed from all others in its depth; its peculiar covering of overlying muscles with the danger of destruction of the nerve supply; and also in the fact that the joint itself could not be exposed by any avenue of approach. The surrounding bone structures only could be reached. It became important, therefore, to carefully choose the entrance according to the special conditions for which operation was undertaken, and the special part of the joint or its surrounding structures it was intended to attack; and that it was necessary to effect an approach by one of the intermuscular routes. The different avenues of approach were considered with the special parts of the joint to be reached by each and some of the special operations for which these different routes might be used. Special consideration was given to the approaches for the use of modified Gant and for arthrodesis of the hip-joint.

Dr. Davis wished to know how Dr. Brackett fastened the upper extremity of the trochanter after it had been

loosened and replaced. If the trochanter were not removed, as good access could be obtained anteriorly as laterally.

Dr. BRACKETT, in closing, stated that his operation did not interfere with the muscular attachments. The patients stayed in bed a few weeks and the trochanter was healed.

Traumatic Arthritis as a Late Complication of Fractures of the Upper Extremity.—Dr. PRESCOTT LE BRETON of Buffalo said that this was a form of arthritis of the hand and wrist beginning several weeks after fracture had occurred. It was characterized by pain, edema, and stiffness of many joints. The course was slow and the recovery imperfect. The lesion was confined to the extremity in which the fracture had occurred. This form of arthritis was not described in literature. He gave the histories of four cases and showed photographs of them.

A Röntgenological Study of Some Brittle Bones.—Dr. ROLAND HAMMOND of Providence stated that osteopathyrosis was divided into two classes, symptomatic and idiopathic. The former included cases of fragility of the bone from various causes; the latter was a congenital condition, probably identical with osteogenesis imperfecta. It was only by a microscopic examination that one was able to make an absolute diagnosis in a given case: but, as not all cases could be investigated histologically, röntgenography afforded a valuable method of studying them. The prognosis for life was good in all these cases. The treatment should be directed to the upbuilding of the general health. It was usually necessary to continue artificial support for the legs by means of braces for many years, and practically permanently. Deep massage or vibration and the use of some form of electricity stimulated the circulation and tended to restore tone to the muscles.

The Adolescent Tibial Tubercle: an Anatomical and Pathological Study.—Dr. JOHN DUNLOP of Washington, D. C., stated that lesions of the tibial tubercle were far more frequent than the literature would go to show and included strains or sprains as well as fractures. From a thorough study of the literature and personal observations it would seem that the border line between the so-called inflammatory lesions of the pretibial tubercle and the actual separation of the tubercle was one of convenience. The usual type of development was in three sections: proximal, medial, and distal. The form or development had a bearing on the nature of the injury. The right side was more open to an injury than the left, owing to the more advanced development of the muscles of the right side. The etiological factor seemed to be a quick muscular action on a thin layer of cartilage and most frequently at a period in development when the cartilaginous space was least before union had taken place. Girls, as well as boys, might be affected; and they were more liable to affections at a somewhat earlier period on account of the earlier development of the tubercle. The symptoms were pain at the tibial tubercle, usually confined to a small area, and decreased ability to use the limbs, especially where much muscular activity of the thigh muscles was required. The *x*-ray was indispensable in the diagnosis and correct understanding of the case. The treatment was partial fixation and general toning up of the joint, and required from six weeks to several months, depending upon how soon after the accident the lesion was recognized.

An Unusual Pathological Condition of the Sacroiliac Joint, Causing Sciatica.—Dr. SYDNEY M. CONE of Baltimore said that there were various pathological conditions of structures neighboring on the sacral plexus and sciatic nerve itself which caused symptoms of sciatica. Besides confirming several of these conditions he added two new cases, one of osteophytic growths following a railroad accident to a healthy man aged 34, in which he injured his left pelvic region, and after lying up a long time was treated for sciatica and sacroiliac loose joint for several years. *X*-ray examination and physical examination showed bony growth about the sacroiliac joint. At operation several bony growths were removed at this joint and about the great sacrosciatic notch. The patient was promptly relieved. The second case was treated for a year or more for a loose sacroiliac joint. The *x*-ray showed thickening (a cloudiness) of the tissues above the acetabulum of left hip. Exploratory operation showed the joint to be normal, but the periosteum was thickened and chronically inflamed. Operation revealed a thickened periosteum and a small osteophytic growth at the great sacrosciatic notch. Curetting of this resulted in complete relief from all symptoms.

Further Study of the Lumbosacral Articulations, with a Consideration of the Importance of the Articulations Formed Between Transverse Processes of the Fifth Lumbar and the Sacrum.—Dr. JOEL E. GOLDTHWAIT of Boston reported that three cases were seen within one year, one of which was operated on by him, with the result of correcting the condition, which was very common. He considered this joint as definite as any in the body. He stated that as people became heavier they often got sciatica; because the weight of the body pressed upon these articulations. Anything that increased lordosis would bring the spinous processes nearer together and pinch the nerves. If by means of exercise, one could get heavy people to stand correctly, so as to pull these processes apart, one could relieve their symptoms. Otherwise one could cut the process off, which was not a difficult thing to do.

Peroneal Spasm.—Dr. CHARLES F. PAINTER of Boston stated that the rigidity of the peroneal muscles was very difficult to overcome. He had found in the tendon sheath, just where it began to play into the groove, an articular facet, which was not a part of the groove; and in the tendon there was a body that could be distinctly felt, causing the tendon to expand in both directions. He dissected this body out and left the tendon intact. He afterward left the foot entirely free. The second day after the operation he could move the patient's foot in any direction and there had been no recurrence. In view of the anomalies that anatomists had found to exist in the tarsus, he thought that this might be a possible explanation of the condition.

Dyschondroplasia.—Dr. CLARENCE E. COON of Syracuse said that the patient was normal on one side. The right arm was shorter than the left. There was no interference with the joints in any place except on the tip of the olecranon and the tip of the acromion, where there were growths. The right lower extremity was three inches shorter than the left, but no masses could be felt on this extremity. The right foot was slightly smaller than the left. By means of the *x*-ray much more extensive bone changes were observable than could be seen on a surface examination. There were three distinct bone changes present in the same individual: cartilaginous tumors, exostoses and changes in the bone presenting the appearance of striations.

Mutton Tallow and Iodine as a Substitute for Bismuth Paste.—Dr. DAVID SILVER of Pittsburg said that mutton tallow had been used because it was felt that an animal substance would be a better material to inject into the body than a mineral. It was generally supposed that mutton tallow became rancid easily, but a specimen that he had had for a long time in his desk had failed to show any evidences of this. The sinuses in which this substance was used were distinctly drier than are those injected with bismuth paste. This fact also made the tallow better than vaseline.

Pathogenesis of Spur Formation on the Os Calcis.—Dr. Roland G. Meisenbach of Buffalo exhibited the radiograms of a series of cases showing spurs in different stages. A careful interpretation of the radiogram of the foot might assist in the diagnosis of the cause of the spur. The symptoms were not due to the size, as was generally supposed, but to the cause. When the spurs were in the advanced stage and large, removal of the spur by excision was indicated. The spurs seemed to be actual bone formations and not periostitis. The symptoms were not due to the size of the spur, but to the cause producing it, which might be thymus infection, osteoarthritis, or syphilis.

Dr. Philip Hoffmann of St. Louis believed that these spurs were often the residual product of an inflammation, possibly a periostitis, of the os calcis, which was frequently accompanied with a periostitis of other bones. He considered it unwise to remove the spurs as long as there was tenderness anyhere else about the bone.

Dr. J. P. Lord of Omaha said that if one observed this remarkable specimen, it would be noticed that it was a diffuse and general process and must have had its origin in the periosteum. That the muscle traction did have its influence, however, could not be denied; though it would seem to be only a minor traction in cases of this general diffusion of the process.

Dr. Truslow stated that many patients objected to undergoing an operation, and that by carefully hunting out the tender plants many of these could be relieved by means of proper foot-plates.

Dr. Albert H. Freiberg, of Cincinnati, had seen a good many of these cases that he thought were of traumatic origin, and others that he considered inflammatory. He had had to operate on but one, however. He had found that after wearing an athletic shoe with the heel removed, for several months, the patients were able to discard this style of footwear without producing a return of the symptoms.

Dr. Kiely said that any one that had worked in the dissecting room would recognizze the fact that there was a great variation in the size and form of the tuberosity.

Dr. Colvin stated that Achilles bursitis was occasionally accompanied by spur formation. The spurs were end products, and did not harm. The advanced cases of this bursitis, however, were not cured until the bursæ were removed.

Dr. Cone remarked that wherever there was a functional use of a part there would be bone formed, if there was a congestive condition present.

Dr. Ryerson had operated on a number of these cases. At first the results seemed so promising that he thought the operation would be universally curative. One patient, however, had been operated upon for the third time for this condition, and was awaiting an operation for a fourth spur which had formed in the same place as the others.

Dr. Virgil P. Gibney of New York City felt a little skeptical as to the value of shaving off these spurs.

Dr. Freiberg asked Dr. Ryerson whether he had made any attempt at a wide excision of the soft parts around the spur. If this were done the metaplasia might not be reproduced.

Dr. Ryerson said that it was difficult to take off a spur without excising a little tissue around it. He believed that a great many of these cases were due, not to the gonococcus, but to the *Bacillus coli communis*.

Dr. Meisenbach, in closing, stated that it was difficult to determine whether the condition was one of periostitis or bone-growth.

An Operation for Severe Grades of Contracted or Clawed Toes.—Dr. Philip Hoffmann of St. Louis said that the operation that he had used for the correction of this deformity was not so formidable as it appeared, and he thought that they would have no cause to regret giving it a trial. He sewed the wound up with catgut and put on a sterile dressing. In a week or so the tendons were found relaxed and there was perfect movement.

Dr. Clarence L. Starr of Toronto asked whether practically all of these cases were not paralytic. He thought that some cases might be purely traumatic and not have the condition that these feet presented.

Dr. Ryerson said that this operation seemed most rational. He had done fifteen of the Sherman operations, with various modifications. The results in several cases were good, but in others not so good. While this operation at first sight seemed rather formidable, he thought that one could accept Dr. Hoffmann's results as pretty conclusive.

Dr. Freiberg asked Dr. Hoffmann to tell him whether he would prefer this operation in cases in which claw deformity had resulted from infectious arthritis, and in which the toes grew stiff in the extended position.

Dr. Hoffmann, closing, stated that he did this operation only in those severe grades of the condition in which one could bring the toes and the bases of the phalanges into contact with the distal surface of the metatarsal bone. He thought it adapted to all severe grades of the deformity, from whatever cause, either infectious arthritis or paralysis. Only two out of eight cases were due to the latter. The operation was simply to get rid of the metatarsal heads. For milder grades of contracted toes he would not advise it.

Suggestions as to Notes and Records in an Orthopedic Hospital.—Dr. Virgil P. Gibney of New York City said that at the orthopedic hospital at Canton, near Boston, which he had visited recently in company with Dr. Brackett, the doctor in charge showed them the complete system of keeping records. He was much impressed with the value of the system. After returning to New York he visited Bellevue Hospital, and found there also a most admirable system. This system was copyrighted, and any number of the sheets used in it would be furnished to any hospital that chose to take it up.

Dr. H. Augustus Wilson of Philadelphia was especially interested in this subject, because Dr. Coplin, the medical director of the Jefferson Hospital, had made a similar tour of inspection, and had found the expense of establishing such a system to be so great as to be for the present prohibitory. Dr. Wilson mentioned this in the hope of being able to take back to him a statement that his figures were too high.

Dr. Gibney, closing, thought that the expense would largely be controlled by having an efficient superintendent of the hospital. He could often utilize the assistance of convalescents in doing some of this work. The superintendent of Dr. Gibney's hospital had said that it would not be nearly as expensive as had been expected.

A Simple Splint for Snapping Knees.—Dr. A. J. Steele of St. Louis said that in this condition, in which the epiphysis was separated from the diaphysis, he presumed that the ligaments were too long, so that the bone slipped out and was forced back again. It had occurred to him that it must be a lateral slip, and that it would be a simple matter to put a small brace that would not interfere with motion on each side of the knee. He had devised a small sole-leather splint, which his patient had worn continually for five or six months, and the snapping had nearly passed away.

Pott's Paraplegia of One Year's Standing; Laminectomy; Almost Complete Recovery.—Dr. Emil S. Geist of Minneapolis stated that the location was the third and fourth dorsal vertebræ. Laminectomy was done, and an extradural abscess communicating with the posterior mediastinum was found. Drainage was allowed to remain in for three months. A beginning return of sensibility was noted for months after the operation. Motion and sensi-

bility had entirely returned by the end of nine months after the surgical procedure. A brace was applied, and walking begun. The patient had an attack of pneumonia and pleurisy two months later, which ended in death. Dr. Geist exhibited the pathological specimens, gross and microscopic.

Dr. Ruth remarked that it was interesting that a paralysis lasting as long as this could have been followed by entire recovery. He had had a case of nearly duplicate history, in which various means of straightening were tried, covering a period of two years. Each time the procedure was followed by a remission of the symptoms of paralysis. Finally, he did a laminectomy, and hoped to get results as brilliant as Dr. Geist's, which should encourage surgeons to open up these cases otherwise absolutely hopeless.

Dr. Cone said that the textbooks on orthopedic surgery stated that bony pressure was not the usual cause for the paralysis, but that there was inflammation along the membranes. He wished to know whether in this case the cause was bony pressure or the abscess itself.

Dr. Geist, in closing, stated that the larger portion of the abscess was in the posterior mediastinum. As soon as the chisel had penetrated into the spinal canal a drop of pus spurted out at every inspiration. It seemed probable that the abscess was the cause of the paralysis, especially as the cord at that point was much smaller than normal. Such patients would lose very little by submitting to a laminectomy, even if they lost their lives, and they perhaps had a great many chances in their favor if such an operation was performed.

A Modified Genuclast.—Dr. Philip Hoffmann of St. Louis said that it was a great advantage to have a genuclast that was compact and easily sterilized, and could be manipulated and adjusted after it was on the limb. This one answered these requirements and was an improvement in this respect over the models formerly used. The one objection to it was the leather straps. He had thought of using chains, which could be boiled, instead of the straps. However, he boiled the straps. Of course, this spoiled them, and a new set was needed for the next operation. In place of the strap, sterilized gauze might be used.

Election of Officers.—*President,* Dr. Virgil P. Gibney, New York City; *First Vice-President,* Dr. George B. Packard, Denver; *Second Vice-President,* Dr. T. Halsted Myers, New York City; *Treasurer,* Dr. G. G. Davis, Philadelphia; *Secretary,* Dr. Ralph R. Fitch, Rochester, N. Y.; *Member of the Executive Committee,* Dr. Ansel G. Cook, Hartford; *Delegate to the Congress,* Dr. Joel E. Goldthwait, Boston; *Alternate Delegate,* Dr. R. T. Taylor, Baltimore.

Causes Determining the Sex.—L. Billon says that embryological facts show how the spermatozoid and ovule encounter one another, each charged with a certain quantity of sex. From their union life is born. Physiology shows that the ovule is detached and becomes fecundable at the moment of ovulation, about the epoch of menstruation. The elements brought by spermatozoid and ovule are opposite; the testicle is female, the ovary male. Greater quantity of sex in the ovary gives a male, in the testicle a female. Clinical facts show that whenever on account of sickness, age, war, etc., the male is inferior boys are born; but the woman may not be superior to the man on account of sickness, amenorrhea, or the premenstrual period, and conception will be feminine. There are two consequences; the child will resemble morally and physically the stronger parent; the second consequence is autoregularization; the number of increases among animals will be proportional to their mortality; there will be always perfect equilibrium. The child will have the vitality of its strongest parent and the sex of its weaker one; the sex of the weaker will be not only spared but fortified. The generator which is stronger at the moment of conception gives sex to the product, and it is the opposite sex.—*Journal de Médecine de Paris.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended August 26, 1911:

	Cases	Deaths
Tuberculosis Pulmonalis	463	145
Diphtheria	190	19
Measles	129	9
Scarlet Fever	72	4
Smallpox	—	—
Varicella	11	—
Typhoid Fever	143	31
Whooping Cough	43	15
Cerebrospinal Meningitis	5	5
Malarial Fever	—	
Totals	1,056	228

Pertussis and Spasmophilia.—W. Wernstedt notes the resemblance between the attacks of pertussis and those of laryngospasm and the frequency of convulsions in the course of pertussis. On the basis of an increased galvanic excitability in all of these conditions, he concludes that there is a close relationship between pertussis and spasmophilia.—*Monatschrift für Kinderheilkunde.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended August 25, 1911:

ACTION OF COLLOIDAL PLATINUM UPON THE BLOOD IN MYELOGENOUS LEUKEMIA.*

By HUGHES DAYTON, M.D.

NEW YORK.

ASSOCIATE ATTENDING PHYSICIAN, NEW YORK HOSPITAL.

THE action of colloidal metals upon the blood has been studied by a number of investigators, some of whom have employed the chemically prepared colloids, particularly collargol, and others the electrically prepared. Those who have used the latter are divided as to the efficiency of various preparations, some, including Robin,[1] de Laire,[2] Foa and Agazzotti,[3] Bardet,[4] and others, insisting that only those are active which are prepared by Brédig's [5] method without stabilization. Many others, including Achard and Weil,[6] Charrin, Gompel, Monnier-Vinard, Chirié, David, Gaillard, Gompel, and V. Henri,[7] Iscovesco,[8] Stodel,[9] Auboyer,[10] Malaquin,[11] Bourguignon, [12] and Ascoli and Izar, [13] believe that only stabilized, isotonic preparations are active. While Hamburger [14] holds that through the presence of stable colloidal substances, the albumins of the blood serum, collargol does not lose its colloid form when introduced into the circulation, Iscovesco [15] has shown that the addition of blood-serum *in vitro* to non-stabilized colloidal silver causes its immediate precipitation. Stodel [16] claims that, unless made isotonic, colloidal metals are hemolytic. It is now quite generally conceded that colloidal metals are precipitated by salts—electrolytes of opposite sign—and hence by blood-serum. This action may be avoided by the addition of a small amount of a stable colloid, such as gelatin, which renders the colloidal metal equally stable. The preparation may then be made isotonic to human blood by adding sodium chloride, without causing precipitation of the colloidal metal. The advocates of non-stabilized preparations contend that the stabilized are inactive, while the large majority who insist upon the use of the stabilized maintain that this is true of the non-stabilized because of the action of the salts in the blood. The only data concerning the permanence of the injected colloidal metals in the circulation are those of Gompel and Victor Henri,[7] who found more than one part of silver to eighty thousand in the blood of a dog twenty hours after they had injected intravenously 40 c.c. of isotonic, stabilized, electrical colloidal silver. This can, however, hardly be assumed as absolute proof that the metal still retained its colloidal form.

Robin and Weil,[17] using non-stabilized electrically prepared colloidal metals, find that they cause a leucolysis, beginning after one to two hours, and rarely lasting over twenty-four hours, slight in healthy persons, but often intense in affections accompanied by leucocytosis. This is followed by a secondary leucocytosis, usually slight, or by a return to the former level. The leucolysis affects chiefly the polymorphonuclear neutrophiles; secondarily these return to their former proportions, sometimes with eosinophilia. R. de Laire[2] has confirmed these observations with silver, palladium, and gold, noting no individual differences with these metals. Achard and Weil,[6] employing collargol intravenously, found an immediate leucopenia followed by polymorphonuclear leucocytosis lasting about five days, which is substituted by a secondary mononucleosis with eosinophilia. Rodolico,[18] using colloidal silver, did not always find the leucolysis evident or present, and did not constantly observe a leucocytosis later. What increase he did note was in the polymorphonuclears. Bousquet and Roger [19] assert the occurrence of leucolysis, often intense in affections accompanied by leucocytosis, then a secondary leucocytosis. Joltrain [20] notes merely the occurrence of considerable leucocytosis.

On account of this action upon the blood of normal persons and of those with a simple polymorphonuclear leucocytosis, the writer has studied the effect of colloidal platinum on the blood in myelogenous leukemia, having in view the possibility of modifying the blood count and perhaps altering the course of the disease. No cases of lymphatic leukemia have yet been available for such observation. Oettinger, Fiessinger, and Saupher [21] quote Menetrier and Aubertin [22] as stating that the usual reaction to *x*-ray treatment of the spleen in myelogenous leukemia is a short period of polymorphonucleosis, followed by a rapid fall in leucocytosis, and that at the same time the myelocytes and eosinophiles diminish and are replaced by polymorphonuclears. Though the altered blood picture seen in leukemia is probably only a secondary manifestation of an underlying abnormal condition, the fact that exposure to *x*-rays causes in some cases a coincident improvement of symptoms and approach of the blood count toward the normal suggests at least a possibility that the improvement may be dependent upon the blood change.

The writer has employed electrically prepared colloidal platinum made in the Laboratory of Surgical Pathology of the College of Physicians and Surgeons with the cooperation of Dr. William C. Clarke. The distilled water was made in a steamed block-tin still and received in a flask of Jena glass which had been washed with acid and thoroughly steamed to remove salts. The colloidal platinum was prepared by passing a current of about 5 to 6 ampères, 110 volts, between two platinum wires whose ends were placed just below the surface of the distilled water. The platinum wires and the

*From the Medical Division, New York Hospital, and the Laboratory of Surgical Pathology, College of Physicians and Surgeons, New York

inclosing glass tubes, by which they were insulated excepting at their free ends, had been cleaned and sterilized by repeated boiling in freshly prepared distilled water. The colloidal platinum was stabilized by the addition of 0.03 per cent. of gelatin which had been sterilized under seventeen pounds pressure for one-half hour or more on three successive days, and was made isotonic to human blood by the addition of sodium chloride, 7.5 grams per liter. These precautions are necessitated by the fact that heating colloidal metals causes their precipitation, so that all sterilization must be done before their preparation. The colloidal platinum was administered hypodermically in doses of 5 c.c.

The following cases of myelogenous leukemia were observed at the New York Hospital in the service of Dr. L. A. Conner: —

Case I.—P. G., medical number, 19,561, a Russian girl, 18 years of age, single, with no occupation, was admitted March 17, 1910. Her family history was negative. With the exception of measles and scarlet fever in childhood, she had been in good health until three months before admission. At that time she began to have constant pain in the left side of the abdomen, usually dull, occasionally sharp. At the same time she noticed "a lump" in the left side of the abdomen, which had gradually increased in size. She had lost ten or fifteen pounds since the onset of symptoms, and had grown very weak.

Physical examination showed good nutrition, a moist, clear tongue, and enlarged tonsils. The cardiac apex beat was the 5th intercostal space, 8.5 cm. to the left of the median line and quite forcible. Relative dulness extended 2 cm. to the right of the median line; the left border was obscured by the breast. At the apex the first sound was accentuated, followed by a faint blowing systolic murmur transmitted a short distance toward the left; the second sound was short and snappy. The pulmonic second sound was accentuated. A systolic murmur was heard over the whole precordia. The radial pulses were equal, frequent, regular, of fair force and moderate tension. There was some thickening of the radial arteries. Below the left clavicle were slight dullness and sibilant râles on inspiration. Posteriorly, at the left apex were slight dulness and occasional fine subcrepitant râles. At both bases, below the angle of the scapula, were dulness merging into flatness, diminished fremitus, breath and voice sounds (liver and spleen). The abdomen was soft, not tender, with slight dulness in the flanks. Liver dulness extended from the 5th rib to 4 cm. below the costal margin in the nipple line. Splenic dulness was present from the 6th intercostal space to 12.5 cm. below the tip of the 10th rib, and extended anteriorly beyond the median line at the umbilicus. The lymphnodes were not enlarged. The extremities were normal. Examination of the eyes on March 28, by Dr. Colman W. Cutler, showed hyperemia of the right optic nerve; the veins enormously dilated and tortuous, the arteries much less so. Numerous severe flame-shaped hemorrhages were present about the disc. The macula appeared normal. About the same conditions were seen in the left eye, with many small hemorrhages. The urine (March 18 to May 9) was of specific gravity 1.017 to 1.020, acid, amber, with a faint trace of albumin, no sugar, and a sediment of urates.

On March 20 Fowler's solution was given for two days and Beebe's leukemia serum from March 26 to 28. The latter was given again from April 3 to 9, inclusive, and was discontinued on account of a rise of temperature to from 104° to 105° on three successive days, with chill and feeling of extreme illness on April 9. Fowler's solution was again administered in doses gradually increasing from 2 to 4 minims after meals from April 19 to 30. The blood counts on four days during this time are shown in Table I for the purpose of demonstrating the variability in the leucocyte and differential counts. Examination of the spleen on April 16 showed that it extended downward to within 7 cm. of the level of the anterior superior iliac spine, and to 3 cm. below the umbilicus; anteriorly it emerged from beneath the costal margin at a point 5 cm. to the left of the median line, and at the level of the umbilicus extended 2 cm. to the right of that line. On April 29 the general condition was practically the same as on admission, except that the weight had fallen from 96.5 to 91.5 pounds, and the patient complained of frequent tinnitus and also of dizziness when sitting. During her entire stay in the hospital she suffered from frequent headache, pain in the splenic region, and weakness.

From April 29 to May 6 she was given stabilized isotonic colloidal platinum, 5 c.c. hypodermically daily, and from May 7 to 13 the same dose every other day. During this time there was no change in subjective symptoms; and no constant effect on temperature, pulse, or respiration followed the administration of the individual doses of colloidal platinum. During this course of treatment and for a week subsequently the temperature ranged about 1° lower than at any time previously, running, with the exception of a single rise to 102.2°, between 98° and 100.4°: whereas its former range had been 98° to 102° if we disregard the changes due to the leukemia serum. The highest temperature was recorded between 3 and 9 P. M., regardless of the hour at which the colloidal platinum was given. The respiration, previously 24 to 28, ranged between 24 and 36 during this time; the pulse, previously 92 to 116, varied from 80 to 120. Like the temperature changes, these variations were independent of the individual injections of colloidal platinum. The spleen increased progressively in size until discharge on May 20, when it filled practically the entire left half of the abdomen and extended into the right, and was still painful.

The blood was examined on April 30, just before giving the first dose of colloidal platinum, and six hours later; on May 7, six hours after administration; on May 9, forty-nine hours after the injection; on May 17, four days after the last dose. The counts, which, to avoid personal variation, were all made by Dr. H. E. B. Pardee of the House Staff, are shown in Table I.

The variation in the total leucocyte count at times before giving colloidal platinum and at periods six hours, two days, and four days after its administration is less than that which occurred during the preceding serum treatment. There was a slight reduction in the count six hours after the first dose of colloidal platinum, and subsequently a rise during the course of treatment; but the count four days after the last dose was approximately the same as two months before. The polymorphonuclear leucocytes, which were 43.5 per cent. before the injections of colloidal platinum were begun, showed a fall to 33 per cent. six hours later, with a corresponding rise of neutrophile myelocytes from 46 to 61 per cent. One week later, after daily administration of colloidal platinum, the polymorphonuclears had risen to 37 per cent., and after a period of

forty-nine hours more without an injection, to 41 per cent. The same percentage was present four days after the last injection and corresponded closely with that, 43.5 per cent., recorded before the treatment was begun.

Case II.—T. L., medical number, 19,093, a married Italian woman, 45 years old, with no occupation, was admitted April 15, 1910. Her family history was negative. She had often been constipated, but otherwise healthy until three months before admission, when she noticed a large swelling in the left side of the abdomen, which gradually increased in size. She had had little pain, but constant dragging sensation in the region of the tumor. She had grown weaker during the past three months but had noticed no loss of weight.

Physical examination showed some emaciation, skin wrinkled and yellowish; mucous membranes pale; tongue moist and coated, the scleræ subicteric. The cardiac apex beat was felt in the 4th intercostal space, 9.5 cm. to the left of the median line. Relative dullness extended from the right border of the sternum to 10 cm. to the left of the median line. The heart action was regular. At apex the first sound was fairly loud, followed by a loud blowing systolic murmur transmitted a short distance to the left and heard all over the precordia. The pulmonic second sound was slightly accentuated. The radial pulses were equal, regular, rather small, of fair force and moderate tension; the radial arteries were not thickened. The chest was narrow, with a depression above and below the right clavicle. There were some impairment of motion of the right side and, anteriorly, impaired resonance below the right clavicle. Posteriorly there was dulness at both bases (liver, spleen). The abdomen was soft, prominent, slightly tender in both upper quadrants. Liver dulness began in the 5th intercostal space. The sharp, hard edge was felt 10.5 cm. below the costal margin in the right nipple line 10 cm. below the ensiform. The surface of the liver was smooth. The spleen, hard, smooth, and tender, occupied the whole left side of the abdomen, extending to within 3 cm. of Poupart's ligament. The lymphnodes were palpable in the groins and posterior cervical region. The extremities were normal. Examination of the eyes on April 25, by Dr. Colman W. Cutler, revealed very large and tortuous veins in the right eye, the arteries relatively not dilated, and a few very small retinal hemorrhages near the nerve, the edge of which was somewhat blurred on nasal side; the nerve was not swollen. The left eye showed the same condition. Between the nerve and the macula was an oval hemorrhage with white center. Another similar patch was present. The urine from April 16 to May 10 was of specific gravity 1.017 to 1.026; acid; amber; usually turbid; always with a variable trace of albumin; no sugar; usually containing a sediment of urates; with an occasional hyalin cast in one specimen. From April 16 to 26 the urine was at times clear; at others it contained blood clots, or a clear catheterized specimen was reported as followed by the passage of a clot. A few days later the stools were blood-streaked. The rectum showed internal hemorrhoids and blood clots.

Stabilized isotonic colloidal platinum, 5 c.c. hypodermically, was given daily from April 16 to May 4, inclusive. No change occurred in subjective symtoms, excepting that the patient said that she felt better after the injections. Fowler's solution, 3 minims three times a day, increasing 1 minim each day, was then ordered. The patient was discharged on May 15. The spleen was gradually increasing in size, very hard, and tender. The general condition was gradually becoming worse. Weight, 90 pounds on admission, reached 100.5 one week later, and was 99 at the time of discharge.

The colloidal platinum was given at various hours between 6 A. M. and 8.45 P. M. No definite relation was noted between the time of administration and the temperature curve, which ranged between 98° and 103°, always rising above 100.2° and usually above 101° between 12 M. and 9 P. M. The highest afternoon temperature (102.6° to 103°) occurred on the four days following discontinuation of colloidal platinum, subsequently running between 100.4° and 102°. Respiration was usually 20 to 26, rarely up to 32 or 36; pulse 72 to 100, rarely higher (116). No change in either constantly followed the administration of colloidal platinum.

The blood counts are shown in Table II.

Table 2.

	Before Colloidal Platinum.	6½ Hours After Colloidal Platinum.	24 Hours After Colloidal Platinum.	24 Hours After Colloidal Platinum.	2 Days After Colloidal Platinum.	11 Days After Colloidal Platinum.
	April 16.	April 16.	April 17.	April 27.	May 6.	May 15.
Red cells	2,768,000	2,730,000	.....	2,470,000	.....	.....
Leucocytes	312,000	404,000	376,000	400,000	334,000	550,000

Eosinophile myelocytes	3	3	2	....	1.5	1
Mast cells	13	6.5	6	2	6	6
Nucleated red cells	Many	....	..	Present	...	Many

Comparing the blood changes in the two cases reported, the only correspondence in results is a fall in polymorphonuclears from 43.5 per cent. to 33 per cent. in the first, and from 36 per cent. to 27 per cent. in the second, about six hours after the first injection, with a simultaneous increase of neutrophile myelocytes from 46 per cent. to 61 per cent. and from 47 per cent. to 60 per cent., respectively. In the former case the total leucocyte count was slightly diminished; in the latter it was distinctly increased. In both there was a coincident temporary fall in mast cells. In both cases a tendency was shown to return to the condition preceding the injections two days after they were discontinued. In Case I the differential count on May 9 was practically identical with that of March 23, and nearly the same as that of April 30, and this persisted two days later. In Case II the percentages on May 6, two days after the last injection, were practically the same as regards neutrophile myelocytes as before the first injection, and showed a slight rise in polymorphonuclears; nine days later the polymorphonuclears were about the same as at the time of the first count, though the total count and neutrophile myelocytes had increased and the patient was gradually becoming weaker.

The temporary fall in polymorphonuclears after injection of colloidal platinum corresponds with the results observed by others in normal blood and in cases with polymorphonuclear leucocytosis, but there were no uniform coincident fall in the total count and no subsequent marked polymorphonuclear leucocytosis.

Summary.—Temporary leucolysis followed by polynuclear leucocytosis is reported as caused by injection of colloidal metals into normal blood or that showing polymophonuclear leucocytosis. If polymorphonuclear leucocytosis could be induced in this manner in myelogenous leukemia by such injections, one might cause replacement of myelocytes by polymorphonuclear leucocytes, which change is said to accompany the improvement in this disease under x-ray treatment.

The writer has administered isotonic, stabilized, electrically prepared colloidal platinum, in doses of 5 c.c. hypodermically daily or every two days, to two patients with myelogenous leukemia. No constant effects upon temperature, pulse, respiration, or subjective symptoms were noted, and the disease apparently progressed as usual. The only correspondence in the blood changes with those reported as occurring in normal blood or that with polymorphonuclear leucocytosis was a temporary fall in the percentage of polymorphonuclear leucocytes, but this was not accompanied in both cases by a fall in the total leucocyte count. The neutrophile myelocytes coincidently rose and the mast cells fell. Aside from these changes, the variations in the blood were no greater than are common in this disease.

CLINICAL USES OF THE SPHYGMOGRAPH.*

By RICHARD VAN SANTVOORD, M.D.,

NEW YORK.

In attempting to demonstrate the practical utility of the sphygmograph to an audience, many of whom are presumably a little rusty on the subject, it seems desirable to begin with some elementary considerations. Arterial pressure is the lateral thrust of a column of fluid compressed between a force consisting of the ventricular contraction and postsystolic arterial recoil acting on a mass of blood and a resistance due mostly to the friction of the blood in the vessels. It is obviously proportioned directly to this friction, which increases and diminishes with the rapidity of the blood current. This rapidity depends on two factors, the cardiac output and the size of the blood channel. An arterial sphygmogram is an approximately accurate record of the variations of arterial pressure during

Fig. 1.

several successive cardiac cycles. A sphygmograph consists of a lever, the short arm of which is pressed over the vessel to be tested, the long arm carrying the recording apparatus. The amplitude of the tracing depends on the relative lengths of the arms of the lever, the size of the vessel, the variations in the arterial tension, the exactitude of the placing of the receiving pad over the vessel, and the degree of pressure exerted on the vessel. Too great pressure tends to suppress the weaker elements of the tracing, too light pressure fails to develop the stronger. The best results are to be obtained by varying the pressure during the application of the instrument. Apparent contradictions in its renderings are due to lack of skill in its adjustment. The length of the tracing depends on the frequency of its ventricular contraction and the rapidity of the motion of the recording paper.

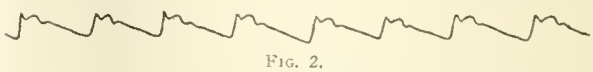

Fig. 2.

There are four factors which influence the shape of the tracing, viz., the amount of blood thrown into the aorta at each ventricular contraction, the condition of the aortic valve, the elasticity of the great vessels, and the state of the peripheral circu-

*Read before the Medical Society of Greater New York, April 17, 1911.

lation taken as a whole—not only that distal to the vessel under examination. Relaxation of the splanchnic vessels for instance, will lower the tension in the radial artery, just as opening a faucet in the kitchen will lessen the water pressure in the second story. A normal radial sphygmogram (Fig. 1) consists essentially of an almost vertical upstroke, a somewhat acutely rounded primary wave followed by a notch and a second elevation, known as the tidal wave, at a considerably lower level, a second notch (the dicrotic) marking the end of the ventricular systole, and a third well-marked elevation, produced by the recoil of the great vessels, known as the dicrotic wave. All the tracings used for illustration were taken with the Dudgeon instrument.

Increased peripheral resistance causes lessened amplitude of the tracing from lessened variation in the tension and often lessened diameter of the artery. The tidal wave and the dicrotic notch appear higher in the tracing and the line of descent is

Fig. 3.

gradual. The tracing shown (Fig. 2) is from a case of nephritis in a young subject. The sphygmomanometer in such a case would show abnormally high tension, which the sphygmograph shows to be postsystolic as well as systolic. A tracing taken from a case of tetanus (Fig. 3) shows the faintly indicated tidal wave at a higher level than the primary and the high position of the dicrotic notch, characteristic of high tension from increased friction of the blood current in contracted normal vessels. Lessened peripheral resistance shows an increased amplitude of the curve from increased variation in the tension and larger size of vessel, after an ob-

Fig. 4.

literation of the tidal wave, low position of the dicrotic notch, and increase in size of the dicrotic wave, as shown in this tracing taken from a case of acute lobar pneumonia (Fig. 4). The sphygmomanometer may show a low normal or even increased systolic pressure. Diminished elasticity of the great vessels produces a flat-topped systolic tracing or one in which the primary and tidal waves are fused into an obtuse rounded curve (Figs. 5 and 6). The flat-topped tracing is often initiated by a sharp point due to an oscillation of the spring of the instrument caused by the very sudden rise in tension. The dicrotic notch is low down and the

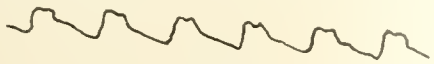

Fig. 5.

dicrotic wave greatly lessened or suppressed, owing to the small amount of blood forced into the periphery by the inelastic great vessels. The sphygmomanometer in such cases, provided the cardiac output remains normal, shows an abnormally high pressure because, owing to the lessened distensibility of the great vessels, a larger portion of the blood mass is forced into the peripheral vessels during ventricular contraction, resulting in increased velocity of the blood stream. The sphygmogram shows that the postsystolic tension falls rapidly below normal.

The effect of a narrowing of the aortic orifice (Fig. 7) is to cause obliquity of the first line of the tracing, as in the example shown. Lesions of the aortic valve capable of causing systolic murmurs are very common, but stricture sufficient to cause an influence on the sphygmogram are not often seen. A tracing taken from an artery into which the flow of blood is impeded from any cause, as so frequently happens in the left radial in cases of aneurysm of the thoracic aorta, shows a similar tracing

Fig. 6.

contrasting markedly with that taken from the other radial. Aortic regurgitation shows a tracing of large amplitude, low position of the dicrotic notch, and the diminished indication of the dicrotic wave, the extent to which these latter characteristics are developed furnishing a measure of the leakage. In the tracing shown (Fig. 8) the sphygmomanometer showed a pressure of 245 mm. of mercury. The postsystolic portion of the tracing falls off because the postsystolic arterial recoil forces back a large percentage of the blood into the heart instead of into the vessels. This case is an illustration of increased arterial pressure due to increased ventricular output. In a case of compensated aortic regurgitation the left ventricle is dilated and the blood mass thrown into the aorta is abnormally large, friction, and, therefore, pressure rises during the cardiac systole. But this increase is offset by the lessened postsystolic pressure. A tracing taken

Fig. 7.

from a case of aortic regurgitation in which compensation was failing (Fig. 9) shows the sharp summit due to oscillation of the spring of the instrument, badly sustained systole, low position of the dicrotic notch, barely indicated dicrotic wave. The effect of aortic regurgitation an the postsystolic portion of the tracing is the same as lessened elasticity of the great vessels. In this case probably both conditions were present. The sphygmomanometer shows a systolic pressure of 200 mm. of mercury. When the heart weakens and the cardiac output becomes abnormally small blood-pressure and its variations may become too slight to overcome the inertia of the instrument and it may be impossible to take a satisfactory tracing.

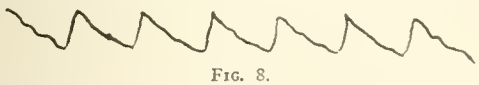

Fig. 8.

After the above exposition we are in position to state that low postsystolic pressure may be due to three factors: low peripheral resistance, inelastic arteries, aortic regurgitation, or any of these combined. The following case illustrates the necessity of recognizing the condition and of diagnosing its cause. This sphygmogram (Fig. 10), taken from a man of 70 without valvular lesion, shows a low

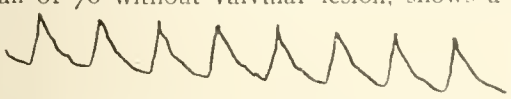

Fig. 9.

postsystolic tracing with a dicrotic wave suggestive of the low tension being due in part at least to relaxation of the peripheral vessels. The sphygmomanometer showed a pressure of 180 mm. of mercury. Three days' treatment with bromide of sodium and ergot relieved him of all his unpleasant symptoms, slowed his pulse from 80 to 60, and

produced the following change in his sphygmogram (Fig. 11) to show the primary and tidal waves on the same level and very marked rise in the postsystolic portion of the tracing, which could be due to nothing but a material increase in his peripheral resistance and was accompanied by a reduction of his systolic pressure to 159 mm. of mercury. The explanation of this apparent contradiction probably is that the high pressure with relaxed vessels was due to increased cardiac output, rendered necessary in order to maintain adequate average pressure in the vessels. When normal contraction of the vessels at fault was brought about the cardiac output was reduced more than

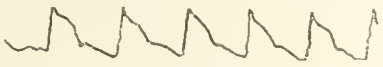

Fig. 10.

enough to offset the effect of the contracted vessels. The heart works with least effort when a certain medium contraction of the vessels exists. Excessive vascular relaxation calls for excessive cardiac output to maintain adequate pressure in the arteries, as seen especially in pneumonia and other acute infections. Excessive vascular contraction calls for excessive exertion of the ventricles with each systole.

As the question of cardiac irregularities will presumably be considered in connection with jugular tracings, I will not go into it. In the above scanty outline of my subject I hope that I have made it clear that the sphygmograph enables us to recognize three distinctly contrasted types of arterial high pressure. One confined to the systole followed by postsystolic low pressure with feebly developed or absent dicrotic wave and due to inelastic great ves-

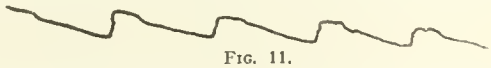

Fig. 11.

sels, aortic regurgitation, or both. High pressure in these cases is distinctly compensatory and to be let alone. Next a high systolic pressure with low postsystolic pressure and good preservation of the dicrotic wave, due to increased cardiac output called for by undue relaxation of peripheral vessels. As in the illustration given this pressure may be reduced by restoring the peripheral vessels to their normal tonicity. Compensating cardiac output is not, however, always found in this connection, especially in acute maladies. The third type shows an increase of pressure throughout the cardiac cycle due to contraction of peripheral vessels, and forms a distinct indication for treatment. These fundamentally important distinctions the popular sphygmomanometer, which indicates with reliability only the maximum pressure, does not make for us. Without the interpretations of the sphygmographic tracing, its renderings may be positively misleading.

10 West One Hundred and Twenty-second Street.

Torsion of the Pedicle of Ovarian Cysts.—P. Gorse finds that torsion of the pedicle in ovarian cysts is not very infrequent, especially in the dermoid variety. The causes of this condition are not really known, but seem in great part to be mechanical. They result in a sudden and agonizing set of symptoms, ending in gangrene or peritonitis, if the twisting is acute, or a slower and less painful and dangerous condition, with edema of the cyst and in some cases intestinal obstruction. Adhesions may be a serious obstacle in dealing with this condition. Appendicitis may be simulated. If it comes on rapidly we get all the symptoms of shock, and gangrene may follow rapidly. Operation should be done at once, since on its early performance depends the life of the patient.—*Le Bulletin Médical.*

MICHAEL SERVETUS AND THE DISCOVERY OF THE CIRCULATION OF THE BLOOD.

By JOHN KNOTT, A.M., M.D.,
DUBLIN.

By one of those curious coincidences of dates, with which the observant reader cannot fail to be impressed after a certain range of experience, the same year of grace—1509—witnessed the birth of Miguel Serveto and of Jean Chauvin, who are probably recognizable by the intelligent man in the street only when set forth with their Latinized cognominal labels of Servetus and Calvin[us]. The Spanish province of Aragon claims the former as a native. The latter first saw the light in the old French province of Picardy, and the story of his life career displays the continuous influence of his native Gallic clearness of thought and restless energy of action, unhappily tinted—and far too deeply—with an atrabiliary and unfading personal hue which gave a painfully characteristic color to all his conceptions of Christian doctrine and ideas of social duty. The lives of Servetus and Calvin were spent in an epoch of seething—even violent—intellectual unrest, which wound up every mainspring of human thought and action to a state of the highest tension, that threw all the more violent and explosive mental and social forces into states of abnormal, and even convulsive, activity. Calvin changed his original career of lawyer for that of theologian. Servetus was very evidently formed by fate for the life of a lonely and mysterious wanderer, who lived only for the sake of the knowledge which he so enthusiastically labored to accumulate. The *learned* were then few in number, and formed a class (very much, indeed) apart from the almost equally illiterate groups of the *nobility* above and the *vileings* beneath. Learning then occupied a position of lofty and acknowledged dignity, which has been sadly lowered by the growth of mechanical knowledge and materialistic principles. The University of Paris was then a focus of intense intellectual activity and curiosity, and the insatiable intellectual greed of Servetus would seem to have been the determining factor in his choice of the study of medicine—as the widest and most fertile field available for the unstinted application of the special abilities and industry of the enthusiastic votary of knowledge in all its aspects. By one of the gloomy freaks of Fate, Calvin "was about" during a part of the period of the medical curriculum of his Spanish contemporary: argumentative, logical, and self-confident, as subsequent events showed that he was specially constructed and foreordained to be throughout the course of his earthly pilgrimage. The ardent intellectuals managed to collide and a challenge to public debate was issued, but Servetus seems to have evaded the tournamental display. The facts were, however, never forgotten by either party. Calvin adopted a theological career, but the unrestrained independence and originality of his views soon made his residence beyond the French border an essential condition of "survival." So he settled in Geneva, the most central of cities of refuge, where his unrivaled devotion to his calling and skill in logic, as well as enthusiasm in dogma, established his position of "Protestant Pope" in the course of a few years. The more orderly of the weirdly incompatible human ingredients of Geneva

society found it advantageous to avail themselves of his leadership. His legal knowledge was found specially useful in the preparation of a new code of law for the community of whose protective shelter he had availed himsef. He reformed the mediæval and semi-barbarous system which had been submitted for his supervision, but—was it his prophetic spirit (or demon) or the evil genius of Servetus which induced him to leave the diabolical clauses and provisions of the text of the pre-existing law of *heresy* quite intact, in all their blood-curdling severity?

Michael Servetus was a votary of knowledge for its own sake, if there ever was one. He, of all men of his generation, could, I believe, most truly say of himself that he "had taken all knowledge for his province," and with a degree of success which attained a higher standard than that of any of the other candidates in the same field. Like other enthusiasts in the persistently successful pursuit of the deadly apple, he seldom failed to bring upon his shoulders the censure of teachers, individual and corporate, who were specially interested in the maintenance of the scientific and logical *status quo* by the exercise of unyielding and uncompromising "authority." Thus, as a newly fledged Doctor of Medicine, he called down upon himself and his novelties of view the red-hot ire of the senior sages of the great Lutetian University, at which he had been an arduously industrious student but a short time before. He deviated soon after into theology, and produced a volume which contained views so erratic on the subject of the Trinity and other sacred questions, that the calorific effect on the French atmosphere become so conspicuous that he found it very necessary to cross over the Swiss border. But his fate there was less auspicious than that of Calvin; his views were as inacceptable to the Swiss heretical doctrinaires as they necessarily had proved to be to the French representatives of orthodox authority. His case was then rather a desperate one; and, as he was very anxious to settle down to the useful practice of the profession to which he was devoted, he assumed the disguise of a new name, recrossed the Helvetian border, and settled down to professional work in the quaint and quiet little town of Vienne; where he was fortunate enough to have a kind and friendly host and patron in the Catholic Archbishop. There he practised the profession of his choice with enthusiastic zeal as well as dutiful attention for some dozen years under the assumed name of Michel Villeneuve (Villanovanus). The *originality* of his theological opinions made it, as he well knew, dangerous to have his identity recognized (under the patronage of a zealous member of the orthodox hierarchy); while, as the event will show, a flight across the border to the general *refugium peccatorum* might prove more dangerous still. But the restless genius of Servetus spurred him continuously along the varied lines of his universal as well as unremitting researches and speculations. He prepared a volume which he very evidently meant to be the crowning labor of his life, and had it privately printed. The subject—and object—were well indicated by the title of "De Christianismi Restitutione." With the sincerity of a candidly honest antagonist he sent a copy of the first few leaves to his old theological opponent, who was immured in the stronghold of his Genevan sanctuary—whence his theological opinions and missives radiated over all Western Europe; for the position which John Calvin had made for himself was a very remarkable one indeed. Servetus reopened the old dogmatic sores, and contradicted the saintly Pontiff of Geneva with the unlubricated emphasis which characterized the controversies of that explosive century.

The Genevan reformer had the specimen leaves of Servetus's book, with all the incriminating private correspondence of the author, placed in the hands of Cardinal de Tournon, who then controlled the machinery of the Inquisition in France. To the highest credit of that Prince of the Church (the fact should be specially noted by all readers interested in the history of human opinion and human prejudice) he laughed to scorn the idea of seriously acting upon the information lodged by a notorious archheretic against a quiet and generally unobtrusive speculator in theological opinion who had never broken with the Church. But the saintly John was far too legally, as well as theologically, bent in mind to allow himself to be permanently held up by an obstructive check of that kind. And his legal knowledge enabled him to utilize the evidence at his disposal by forcing it under the notice of the officials who carried on the work of the Holy Office in France; and in such a way that, as representatives of their function, they were obliged to take notice of his documents and act upon the information which they contained. Accordingly, Dr. Villeneuve was arrested on a charge of heresy and the investigation of his case at once opened. The proceedings seemed to advance briskly for the first few days; then they began to flag. Archbishop Paumier had no feelings toward the studious and inoffensive physician (who had so long been his trusted medical attendant) than those of warm friendship and grateful confidence. The same relationship and feelings had existed between Servetus and the governor of the prison in which he had come to find himself immured through the zealous and skilfully directed efforts of John Calvin. A couple of weeks passed on without very obvious progress, and the prisoner began to feel the *want of exercise*. He asked his gaoler for the key of the garden door, which was given him as a mere matter of friendly civility. There was a terraced series of rising garden beds close to the investing wall, which brought the highest of them to within a few feet of the level of the parapet. And outside there was a convenient buttress. The prisoner ascended by the one and descended by the other, and the interior of the prison of Vienne saw Michael Servetus no more!

Servetus, thus thrown upon the highway of the world, wandered about rather aimlessly for some weeks. We learn that he had thought of going to Italy and there placing himself in temporary contact with the great thinkers of the time. But a curiously fatal fascination drew him toward his old protagonist, the Pope of Geneva, with whom he had "longed long" to break a controversial lance at short range. He entered the Swiss stronghold city of refuge in the darksome evening quiet and immured himself completely for some three weeks. Perhaps his prophetic soul gave foreshadowings of a danger which his own innate ideas of honor and rectitude could not permit him to prefigure. The presence of the new refugee was reported without a moment's delay to John Calvin, who, in his turn, proceeded directly to the public prosecutor and had a warrant made out with all necessary formality. Michael Servetus was condemned and sentenced to the extremest punishment for major heresy known to the darkest legislation of the much-abused Inquisi-

tion. By a curious historic coincidence, to which I have already referred, the Municipal Council of commonwealth of Geneva had chosen the energetic reformer to reform the rather barbaric code of laws by which they had previously been governed. And the fact is well worth noting in this connection that, while he actually wiped out many of its brutalities and softened manifold asperities of its lay practice, he avoided any attempt to repeal the law relating to the extreme penalties for heresy. His prophetic soul was said by many to have foreseen its most desired application, and the blood-curdling fact is authentically recorded that he arranged the place of execution, through his obedient agents, in such a way that he was able to gloat over the scene from the window of the bedroom to which he was confined by the accumulating effects of his life-long *cholelithiasis!* That congenital biliousness, that cumulative force of attack of the ever-recurring *gall-stone colic*—how appropriate a constitutional condition to fostering of the most luxuriating germs of the proverbial *odium theologicum!* Michael Servetus was slowly roasted at the stake with a small supply of fagots, which were purposely chosen *greenish* in quality (so as to insure *slow combustion*). He was *crowned* with a *straw* wreath sprinkled with *brimstone*—which was *first* fired by the executioner's torch. *Tied to his thigh* was the volume which contained his cherished theological doctrines, and the *first printed description of the circulation of the blood* in the human body. Thus was effectively silenced the bearer of the scientific message for the promulgation of which the world was then left to wait for another three-quarters of a century. The *clôture* has rarely been so effectively applied, in the whole of the recorded period of the thorny and stony pathway of the progress of human enlightenment.

Thus did the devoted enthusiast and truthseeker sink below the horizon of human ken, and a definite description of the *pulmonary* circulation went with him into the regions of unknown and unexplored obscurity for a period of seventy-five years. One of the special collateral aims of the present communication is to show that an approximately accurate conception of the *general* circulation remained (as it had been time out of mind) an item of general knowledge. I will now proceed to glance at some items of testimony.

The name (and cosmopolitan fame) of Rabelais must ever retain their magnetism for the inquisitive student—both lay and medical; and the allusion to the same in the discussion of an interesting, and rather tangled, skein of medical history and collateral scientific attainment will surely attract attention—while probably presenting the aspect of an unexpected novelty. To the reader who has some close acquaintance with the history of the dawn and early development of modern science and literature, the name of this (often far too broadly comic) writer at once vividly recalls the restless and curiously inquiring spirit of the age in which he performed his earthly pilgrimage—when the recent introduction of printing, and the almost simultaneous exodus of Greek scholars and Greek manuscripts from Constantinople, which followed the capture of that city by the Turks, had sown all Western Europe with "dragon's teeth." The series of earthquake waves of thought—literary and scientific, political and social, theological and philosophical (moral and immoral)—which immediately arose, and swept the western section of this continent, quickly resulted in the development of intellectual, and consequent social, friction to so great a degree as to raise the temperature of the whole mental, and even political, atmosphere far above the boiling point. And, as invariably occurs during every process of violent ebullition, a large proportional quantity of the veriest intellectual dregs was brought to the surface, and mingled its leaven with the froth and scum which formed the uppermost, and most prominently visible, layer. At the same time the general intellectual activity was necessarily increased to a vast extent; some wonderfully inspired (or inflated) bubbles were thrown up to a great height—and of these a certain proportion flashed forth richly artistic colors before they burst or disappeared; while, during the whole time, the really valuable and wholesome portion of the seething medium was that which remained excluded from the general gaze. François Rabelais was born in 1483, the year in which Martin Luther first saw the light; and he died in 1553, the year in which Michael Servetus was burned for *heresy* at the prosecution of the Protestant pope, John Calvin. Thus his life pilgrimage was performed in a period of which the movements and results were typically characteristic of the Renaissance—its newly awakened Gargantuan freshness and vigor, often spasmodic and even convulsive in the riotous (and therefore inevitably ill-directed) display of the consciousness of its Herculean and Mercurial faculties. The invasion of Europe by the Turks furnished a very ruggedly convincing experience of the possibilities of contact of East with West—a contact which an examination of coincident dates would almost seem to suggest had furnished the impetus that projected the Iberian explorers from the opposite border of the continent on the voyage which resulted in the discovery of the "New World." It unquestionably generated the *diaspora* of Greek scholars and Greek manuscripts, which had the effect of metaphorically realizing the fulfilment of the time-honored Cadmian prophecy. Then directly on the crest of the seismic wave of this epoch-making movement came the invention and universal diffusion of printing with movable types—in the historic wake of which directly followed the series of explosive demonstrations of intellectual unrest that led to the collective result which is historically connoted by the general term *Reformation*. Add to these the introduction of a new (more probably, I believe, a new and foreign edition of an old and worn-out Western) disease, the nature and source of the infection of which made it more cosmopolitan than any other known to the annals of the healing art, and we have displayed a nexus of physical and intellectual conditions which contributed more effectively than all the others known to the history of the human race to the genesis of the primordial germs of our so-called "modern" civilization!

The ordinary lay reader who goes to the works of the famous monk-physician for enjoyment of the buffoonery and obscenity in which, unhappily, a large proportion of his written thought and diction much too largely abound, is seldom cognizant of the fact that the author was one of the most learned men of his generation, and that he had turned from theology and law to the study and practice of medicine, as offering the widest and most fertile field for the cultivation of genuine knowledge which this world offers. Still the fact seems to the present writer not a little remarkable that even

the medical men, who occasionally while away an otherwise heavy evening hour over the fantastic creations of François Rabelais, seldom notice, or but rarely remember, that his great work includes the best compendium of the physiological knowledge of that age that has descended to our twentieth century. I quote from the reprint of Ozell's version which was brought out in 1738 by a prominent Dublin printer and bookseller, Philip Crampton (whose name has been deeply stamped on the topography and professional, as well as literary, history of this city):

"The intention of the Founder of this Microcosm is to have a Soul therein to be entertained, which is lodged there as a Guest with its Host, it may live there for a while. Life consisteth in Blood, Blood is the Seat of the Soul; therefore the chiefest work of the Microcosm is to be making Blood continually At this forge are exercised all the Members of the Body; none is exempted from Labor, each operates a-part, and doth its proper Office. And such is their Hierarchy that perpetually the one *borrows* from the other, the one *lends* the other, and the one is the other's *Debtor*. The Stuff and Matter convenient which Nature giveth to be turned into Blood is *Bread* and *Wine*. All kinds of nourishing Victuals is understood to be comprehended in these two, and from hence in the *Langue Goth* is called *Campanage*. To find out this Meat and Drink, to prepare and boil it, the Hands are put to work, the Feet do walk and bear up the whole Bulk of the Corporal Mass; the Eyes guide and conduct all; the Appetite in the Orifice of the Stomach, by means of a little sourish black Humor (called Melancholy) which is transmitted thereto from the Milt, giveth warning to shut in the Food. The Tongue doth make the first Essay and tastes it; the Teeth do chaw it, and the Stomach doth receive, digest, and chilify it; the Mesaraick Veins suck out what is good and fit, leaving behind the excrements, which are, through special conduits for that purpose, voided by an expulsive Faculty; thereafter it is carried to the Liver, where it being changed again, it, by the Virtue of that new Transmutation, becomes *Blood*. What Joy, conjecture you, will then be founded amongst those Officers, when they see this *Rivulet of Gold*, which is their sole Restorative? No greater is the Joy of Alchimists, when after long Travel, Toil, and Expense, they see in their Furnaces the Transmutation: then it is that every Member doth prepare itself, and strive anew to purify and to refine the Treasure: the Kidneys through the emulgent Veins draw that Aquosity from thence which you call Urine; and there send it away through the Ureters to be slipt downwards, where in a lower Receptacle, and proper for it (to wit the Bladder), it is kept, and stayeth there until an Opportunity to void it out in his due time. The Spleen draweth from the *Blood* its terrestrial part, *viz.* the Grounds, Lees, or thick Substance settled in the bottom thereof, which you term *Melancholy:* the Bottle of the Gall subtracts from thence all the superfluous *Choler:* whence it is brought to another Shop or Workhouse to be yet better purified and refined, that is the Heart, which by its agitation of Diastolick and Systolick Motions so neatly subtiliseth and inflames it, that in the *right side* Ventricle it is brought to Perfection, and through the Veins is sent to all the Members; each Parcel of the Body draws it then into it's self, and after it's own Fashion is cherished and alimented by it: Feet, Hands, Thighs, Arms, Eyes, Ears, Back, Breast, yea, all; and thus it is that who before were *Lenders,* now become *Debtors*. The Heart doth in its *Left-side* Ventricle so thinnify the Blood that it thereby obtains the name of Spiritual; which being sent through the Arteries to all the Members of the Body, serveth to warm and winnow or fan the other Blood which runneth through the Veins: The Lights never cease with it's Lappets and Bellows to cool and refresh it; in Acknowledgment of which good the Heart through the Arterial Vein imparts unto it the choicest of it's Blood: At last it is made so fine and subtle within the *Rete Mirabile,* that thereafter those *Animal Spirits* are framed and composed of it; by means whereof the Imagination, Discourse, Judgment, Resolution, Deliberation, Ratiocination, and Memory have their Rise, Actings, and Operations."

This extract forms what I believe there are good grounds for regarding as the turning point in the historical curve of the discovery of the circulation of the blood, and the most definite connecting link —as well as distinctive landmark—between the medieval physiology and the modern. The skilled reader will readily admit that the *concentrotion* of ideas displayed in the contents of that single paragraph is really amazing. And the charitable critic will not fail to remember that, having regard to the date of its dictation, it was a matter of absolute necessity that a certain proportion of gaseous semi-nonsense should be mixed up with its science. But the wonder surely is that the proportion of the same with which its contents are diluted is actually so small. I venture to express the belief that the skilled reader will regard this paragraph as representing satisfactory proof that Rabelais had very definite ideas, indeed, of the continuous activity of the processes of waste and repair—of absorption, assimilation, and elimination—as they take place in the living human body. Also, that he had a definite notion of the continuous movement of the blood—which was the sole and efficient vehicle of the nutritive pabulum. With regard to the cause of the flow of the moving blood, the knowledge of Rabelais was that of Hippocrates, as then construed by scholars and scientists. There is utter darkness in the room of the "*pulmonary* circulation," and he would seem to have thought that the *veins* conveyed the blood—at least upon occasion—*from the heart* to the distant organs and tissues of the body. But that view must ever remain largely a question of words; the nomenclature of physiological anatomy then abounded in ambiguities, and the reliable medical lexicon of polyglott range and capacity had to wait for some more centuries to be permitted the privilege of exposure to light and air.

The wide gulf in the knowledge of the general or "*systemic* circulation" of the blood which does not appear to have been quite successfully bridged over by any of the ancient investigators, undoubtedly was the *direction of the current in the veins.* But it must be remembered by the open-minded critic that we have hardly sufficient data in the present day to enable us to decide a vexed question regarding the terminology of Hippocrates and the long series of successors who treated his text as *the* infallible authority on matters medical. That the apparent references to *veins* and *arteries* carried the same clearly cut definition of ideas which is conveyed to the mind of the modern anatomist by the connotation of these terms, is a question which might well be raised by a critical opponent of the

affirmative view. The general impression is probably inevitable: that the *veins* also acted—at least, upon occasion—as distributing canals. Of the "*pulmonary* circulation," it may at once be said with the fullest confidence that everything we know of their attainments goes to show that the ancient physicians had formed no conception. And it is on these two heads only: *The continuous direction of the current in the veins* and the existence of a *special pulmonary circulation* of the vital fluid that the "circulatory" ideas of Harvey can be confidently said to have displayed an unquestionable advance upon those of Hippocrates. Accordingly, it cannot fail to interest the inquiring reader, as a true lover of his profession, to have the principal landmarks indicated that were gradually established in the course of the very prolonged pilgrimage which led to the opening of this common gateway of modern physiological knowledge.

The fact that Solomon possessed a competent knowledge of all the details of both animal and vegetable life necessarily included a degree of familiarity with that which forms the subject of the present discussion. Accordingly, as the date of the popularization of the knowledge of the circulation of the blood was also one in which the literal infallibility of the Biblical text was most ardently defended, it is not a matter for surprise that several of the continental European critics of the genuineness of William Harvey's right to the credit of the "*discovery*" vigorously defended the thesis that the latter had really found out nothing that the most learned, as well as wisest, of men had not known thousands of years before. Almeloveen, Bontekoe, Braunius, Hottingerus, Scheuchzer, Witsius and other learned authors of that period which succeeded the publication of the *De Motu Cordis* (in 1628), all rushed into the breach for the avowed purpose of defending and restoring the posthumous scientific reputation of Israel's most accomplished ruler. Some affirmed that he had written fully and lucidly on the subject, but that his physiological publications had inevitably perished; others doubted whether he had really discussed this item of his universal knowledge in written characters, and even undertook to find justifying excuses for the apparent negligence displayed in not doing so.

Curiously enough, Almeloveen also offered (in 1684) an excuse for the comparative negligence of the great "Father of Medicine" in not furnishing to his contemporaries and for the benefit of posterity a more definitely explicit description of the *circulation of the blood*, with which he was surely familiar. His apology for the master is, indeed, a decidedly plausible one; having so many practical subjects and theoretical views to discuss he would not waste invaluable energy and irrecoverable time in the description of details which were really matters of common knowledge. We surely should remember, indeed, when called upon to scrutinize this question with special care, that writers of textbooks and medical monographs in the present day do not include in the texts of their volumes special descriptions of the circulation of the blood. One of the most learned and diligently critical of all the editors of Hippocrates, and one of the most accomplished bibliographers that our profession has ever produced, was J. Antonides van der Linden, and he uncompromisingly upheld the view that Hippocrates was perfectly familiar with the course of the circulatory blood. Indeed, I would suggest that it is very difficult to reconcile the presence of such a passage as the following with any other view (van der Linden's version; *Leidæ*, 1659); "Venæ per corpus diffusæ, spiritum et fluxum, ac motum exhibent, ab una multæ germinautes, atque hæe una unde oriatur; et ubi desinat, non scio; *circulo* enim facto, principium non invenitur." Another passage conclusively proves his knowledge of the origin of the arteries from the heart, and his conception of the action of the latter as the mainspring which furnished the originating central impulse for the movement of the contained fluid: "Radicatio orteriarum cor . ex his aberrant in omnia sanguis, et spiritus, et calor per hæc meat." These passages surely prove the fact that it was not left for Galen to discover that the arteries of the body were not "merely air pipes," as has been ignorantly stated by shallow historians of medical discovery and progress. The first of the preceding quotations, of course, represents Aristotle as believing that the blood, after being carried back to the heart, is "sent by it through the veins over the body." This statement is now familiarly known to be the reverse of physical truth. But if, as is more than probably—almost demonstrably—the case, the good old Stagirite actually used the term there translated "*veins*" for "*arteries*," his knowledge of the cause of the circulating blood was absolutely unquestionable. Indeed, as he applied the word φλεβς, which is habitually rendered by the English equivalent *vein*, to the main arterial trunk (to which he would appear to have been the first to give the name of *aorta*, by which it is now universally known to anatomists), there can be no doubt that he indulged (or was made to by his transcribers) in a careless transposition of terms, which has left the precise degree of his knowledge of the circulation a permanently debatable quantity. But surely the following passage displays a degree of familiarity with the central facts of the mechanism of the circulation as complete as the average physiologist of the present day could well include in the same number of words: "Nam è lateribus venæ magnæ et arteriæ, exiles venæ utrinque derivantur, per obliquum scilicet, et venæ cui libet arteria sua est adjuncta. Quod autem venæ, et arteriæ inter se committantur, sensu quoque ipso manifestum est" (*De Partibus Animalium*, Lib. III). This surmise regarding the variable use of the term "vein" (φλεβς) by Aristotle is rendered still more demonstrable by the fact that Aristotle's former tutor, the "divine" Plato, in a well-known passage of the *Timæus*, refers to the *heart* as the *origin of the veins:* "Cor vero venarum originem, fontemque sanguinis peromne corpus impetu quodam manantis." The term *impetu* (σφοδρως) was surely never applied by the most poetic of philosophers to the slow and undemonstrative movement of the blood in the *veins* —as this term is employed by the modern English-speaking anatomist.

After the immortal Stagirite had been gathered to his fathers his anatomical mantle descended on Erasistratus and Herophilus (whose name is made familiar to every medical student on his early introduction to the osteology of the occipital region). In their day the city of Alexandria, which still bears the name of Aristotle's famous pupil, developed a flourishing School of Medicine, theoretical and practical. And there those two anatomists, under the liberal patronage of the Ptolemies, would appear to have investigated the structure and functions of the human frame with a degree of energy quite unprece-

dented. We read that those pioneers of scientific anatomy and physiology "taught that, while the veins conveyed blood from the heart to the members, the arteries carried a subtle kind of air, or spirit." The statement seems to represent the general belief of what the author of the *Religio Medici* elected to distinguish as the "Learned Vulgar." Indeed, it represents a great deal more than was, I believe, meant by that gifted and earnest writer to be comprehended in the connotation of that highly (and happily) expressive compound term. For I have even this year observed, and with even more pain than surprise—there was, indeed, a good deal of each—that one of the most important of the medical journals of the British Empire states, in a very highly *specialized* article loaded with Italian, and Greek, and historical, and physiological, and philological, and other varieties of learning—medical, scientific, and literary—that "Aristotle believed that the veins alone (not the arteries) contained blood." (!) Such is fame, as interpreted by highly responsible persons in highly representative localities. Such statements and views which are ever and anon being displayed by the "leading" representatives of what is still *nominally* a "learned" profession, and was for centuries one of the most so in existence, has tended to make at least one non-member rejoice in the firm stand against *Modernism* which has been made by the Catholic Church. How utterly the teachings of Aristotle and of his greatest interpreter, St. Thomas Aquinas, have been lost sight of in these countries, since the precocious stripling, Francis Bacon, conveyed to England what scraps and samples of the noisily iconoclastic preaching of Peter Ramus that he had picked up during his two and a half years' sojourn in France, is one of the phenomenal records of negative achievement in the history of the "march of intellect." And the reputation of that amateur reformer of philosophy is based, too, on one of the greatest of the negative achievements of iconoclastic interference—not to say colossal intellectual fraud, and boundless intellectual assumption. How few members of the so-called "learned" section of the citizens of the British Empire at the present day seem to know that Bacon never even mastered the Aristotelian and scholastic philosophy, of which the overthrow was the ultimate goal of his intellectual ambition; and that many of the very best judges of the facts and collateral data now before us are disposed to deny that the famous "Father of Experimental Philosophy" and "Founder of Inductive Logic" was at all capable of accomplishing that intellectual feat even if he had expended all his best efforts in trying! In the departments of *Experimental Science* and of *Natural History*, the present writer hopes that he can lay claim to some little ground for confidence in the expression of his opinion, and he does not fear contradiction in pointing out that the attainments of the famous Lord Chancellor in each of these departments were *too far below* those of the monarch of philosophy, against whom he organized so successful a revolt, to lend themselves to serious comparison. They were not developed even on the same intellectual plane, and no scientific common measure will apply. And after giving what attention and powers of perception that he has found available to the estimation of the relative stature and power of grasp of those intellectual giants, in the departments of the higher philosophy and logical and metaphysical reasoning, he has come to a very similar conclusion. And thus it was that British science and philosophy were originally emancipated, and permitted to develop spontaneously along the lines of amateurish culture. And the new air of *freedom* had, it must be admitted, a certain invigorating quality of its own. Thus the new plants grew rapidly; and, in process of time, all—ran to seed! Probably Robinson Crusoe was a much healthier man after the years of his sojourn in his lonely island monarchy. Nobody will dispute the fact that he was a very much handier one, and dowered with probably unequaled gifts of resourcefulness. But, although his tailoring capabilities gave most effective, as well as picturesque, results at home in his insular residence, they could hardly be profitably floated on the Bond Street Market. Yet such was the strictly comparable result that was realized by the philosophic innovations of England's most famous Lord Chancellor!

It is, of course, well known to inquiring readers that one of the horrors of social, as well as of medical history, is centered in the fact that the indulgent patronage of the Ptolemies placed the living bodies of the very numerous criminals of their misgoverned dominions at the disposal of the anatomical enthusiasts to whom I have already referred, Erasistratus and Herophilus; and that the scientific scandalmongers of the period credited the latter of these—and, I much fear, with far too close an approximation to actual facts—with having *vivisected* no less than six hundred human beings in the course of a single year, I have no hesitation in expressing, with fullest confidence, the opinion that he could not have remained ignorant of the fact that the arteries were filled with blood during life—not merely with *spirit*, in the modern sense.

The main object of these preliminary remarks on the existing evidence of the attainments of the physiologists of ancient times—which, of course, included those of the long series of medieval centuries that accepted their *"authority"* without question—has been to place the views of Michael Servetus in the proper perspective, and against a clearly defined background. These are thus expressed in the volume which initiated the final stage of the author's deplorable fate:

"Ad quam rem est priùs intelligenda substantialis generatio ipsius vitalis spiritus, qui ex ære inspirato et subtilissimo sanguine componitur, et nutritur, vitalis spiritus in sinistro cordis ventriculo suam originem habet juvantibus maximè pulmonibus ad ipsius generationem. Est spiritus tenuis, ut sit quasi ex puriori sanguine lucidus vapor, substantiam in se continens aquæ, aeris et ignis. Generator ex facto in pulmonibus mixtione inspirati aeris cum elaborato subtili sanguine, quem *dexter ventriculus cordis sinistro communicat. Fit autem communicatio hæc, non per parietem cordis medium, ut vulgo creditur; sed magno artificio a dextro cordis ventriculo, longo per pulmones ductus, agitatus sanguis subtilis: à pulmonibus præparatur, flavus efficitur, et à vena arteriosa in arteriam venosam* transfuditur. Deinde in ipsa arteria venosa inspirato aeri miscetur, *et expiratione à fuligine repurgatur.* Atque ita tandem *à sinistro cordis ventriculo totum mixtum per diàstolem attrahitur,* apta suppellex, ut fiat spiritus vitalis.

"Quod ita per pulmones fiat communicatio, et præparatio, docet conjunctio varia, et communicatio, venæ arteriosæ cum arteria venosa in pulmonibus. Confirmat hæc magnitudo insignis venæ arteriosæ, suæ nec talis, nec tanta facta esset, nec tantam à corde ipso vim purissimi sanguinis in pulmones emitteret, ob solum eorum nutrimentum, nec cor

pulmonibus hac ratione serviret: cum præsertim antea in embryone solerent pulmones ipsi aliunde nutriri, ob membranulas illas, seu valvulàs cordis, usque ad horam nativitatis nondum apertas, ut docet Galenus. *Ergo ad alium usum effunditur sanguis à corde in pulmones hora ipsa nativitatis, et tam copiosus.* Item, *à pulmonibus ad cor non simplex acr, sed mixtus sanguine mittitur, per arteriam venosam: ergo in pulmonibus fit mixtio.*"

After its return from the lungs to the left side of the heart, Servetus pursues the blood in its passage along the arteries. He then loses sight of its course, or, rather, allows it to go—he was *not* writing a treatise on physiology. On this account the majority of makers of text books seem to have held the view that he had really no definite idea of the *systemic* circulation. This objection has been reproduced, I venture to assert, in at least 98 per cent. of the cases of its repetition, on second-hand, or hearsay evidence. The conception of the circulation was, as will readily appear to the thinking mind, an *abstract* idea. The mind which could conceive—and so clearly describe—the course of the blood in the *pulmonary* circulation was, most assuredly, capable of conceiving the *systemic*. And I think the reader who has taken the trouble of examining the evidence which I have placed before him, and following the lines of my argument, will have before now agreed with me that there had been some notion of the latter before the medical world ever since the days of Hippocrates; while there has not hitherto been found a trace of the faintest conception of the former. Thus the only reasonable question that can be asked by the intelligent and well-informed skeptical inquirer in this connection, and at this present stage is: *Did he know that, throughout the whole system of venous canals, the blood always flowed in the same direction?* There is, I fear, little likelihood that a completely satisfying reply to this query will ever be furnished. The horrible—and peculiarly isolated—fate of poor Michael Servetus; the almost complete destruction of his "*heretical*" book; the danger signal so clearly flashed forth in its title—all combined to consign the volume to oblivion. Indeed, the wonder really is that the passage which I have quoted was ever disinterred. It thus appears that the fiery zeal of John Calvin, whose atrabiliary enthusiasm recognized no *lawful* restraint in the confident assertion of his own othodoxy, registered the stupendous record of having successfully arrested the course of the indicating hand on the dial of progressive science for exactly three-quarters of a century.

Another pioneer of medical and physical discovery in that generation was the Italian, Andrea Cesalpino (1519-1603), who published (*Venice*, 1571) a remarkable and interesting volume entitled *De Quæstionibus Peripateticis;* wherein the author enunciates with a brevity of expression, too, which only a master of his subject can afford to employ, brilliantly clear ideas of the movements of the blood; but in which he cannot with either justice or accuracy be said to display any substantial advance on the teaching of Servetus. That writer, indeed, does actually apply the now universally recognized technical term to the "pulmonary" *circulation*, which had been so well described by poor Servetus eighteen years before:

"Huic sanguinis *circulationi* ex dextro cordis ventriculo per pulmones in sinistrum ejusdem ventriculum optimo respondent ea, quæ ex dissectione apparent."

The whole paragraph which contains the above sentence is a peculiarly brilliant and interesting one. But a still more remarkable statement appears in another work of the same author (*In Quæstionibus Medicis*); where, after the inevitable discussion of the views of Aristotle, he adds:

"Pro cujus loci explicatione illud sciendum est: Cordis meatus ita à natura paratos esse, ut ex vena cava intromissio fiat in cordis ventriculum dextrum, unde patet exitus in pulmonem: ex pulmone præterea alium ingressum esse in cordis ventriculum sinistrum; ex quo tandem patet exitus in arteriam aortam, membranis quibusdam ad ostia vasorum appositis, ut impediant retrocessum: *sic enim perpetuus quidam motus est ex vena cava per cor, et pulmones, in arteriam aortam*: ut in quæstionibus peripateticis explicavimus."

Every intelligent critic must agree that the passage now quoted contains as perfect a description of the principal nuclear facts of the circulation as any physiologist of the first decade of the twentieth century could possibly include in a corresponding number of words. The writer was, most assuredly, thoroughly acquainted with all the essential phenomena of this, the most important of all the vital processes of the higher animal organism. And, accordingly, having regard to the fact that the enunciation of the same proposition by Michael Servetus was recorded in a document which appears to have then been absolutely lost to the scientific world, and to the supplemental fact that there does not appear to exist a particle of (even circumstantial) evidence which could be brought to prove that Cæsalpinus knew anything of the views of Calvin's victim, I have no hesitation in affirming that his countrymen were able to establish a fair claim for the brilliant Italian, as the first *publisher* of the fact of the circulation of the blood, if not actually its original discoverer. Indeed, the above quotation embodies important items which are not to be found in the incidental reference of Michael Servetus; although, I feel bound to add, the probable reason is that the reference really was *incidental—only*. The single item of uncertainty that remains, in regard to the knowledge of Cesalpino is, as in the case of Servetus, of the *definite direction* of the blood current in *all* the *veins*. And this item of haziness is by no means the important one which a special advocate might readily lead a skilled jury to believe. The general law of the uniform rise and fall of the sea level in all contiguous oceanic areas is not at all affected by the curious physical fact that, in the Menai Strait, the water flows continuously in one direction during the flow of the tide and in the opposite direction during the ebb; although theoretical considerations would lead one, at first thought, to expect that the surface level would rise and fall simultaneously at both ends of the channel. Curiously enough, in the work of Cesalpino from which the above quotation has been taken, is to be found the interesting coincidence of an allusion to a far more monstrous tidal phenomenon, that of the *Euripus*. Its importance is emphasized by the fact that the reference is introduced in the course of a discussion of some of the opinions of Aristotle. It is, of course, well known to the curiously learned that one of the many accounts of the mode of termination of the earthly pilgrimage of the immortal Stagirite is associated with the unique tidal currents of that strait. Having conquered the whole of the known intellectual world as completely as his pupil Alexander did the geo-

graphical, the monarch of philosophy found himself one day, toward the close of the "grand climacteric year," loitering on the shore of the "fret of Negropont;" along which the tide ebbed and flowed, diurnally, no less than seven times. With all the unrivaled intensity of his intellectual powers he concentrated his cogitations on the endeavor to discover the unknown cause of that unique phenomenon. But "the master of those who know" was predestined to find that after laborious and prolonged mental effort, he had still failed to make any perceptible progress toward arrival at the wished for solution; and, as the practical aspect of his philosophy does not appear to have included the stoicism necessary to bear the unprecedented experience of intellectual failure with the appropriate epicurean *tranquillitas*, he walked to the rock-bound margin of the inexplicable gulf, and with the words *si quidem non capio te, tu capies me*, threw himself headlong into its waters. And I would here call emphatic attention to the peculiar suggestiveness of Cesalpino's happily appropriate allusion to the *crux* of the Euripus current. It is very doubtful whether his views, or those of the martyred Servetus, included a solution of the curiously similar Euripus problem of the circulation of the venous blood—as their contemporaries, and perhaps themselves, regarded the alternating direction of its currents in at least some of its containing vessels. Most assuredly, it is *only* in this region that an unsolved problem remained; and, as I venture to trust that I have already convinced the reader, it was the only section of the "systemic" circulation which does not appear to have been grasped by the Father of Medicine himself.

Thus I believe that the only item now remaining for discussion is that of the intravenous *valves*: the discovery and demonstration of their existence, and the assignment of their function. They appear to have been known to the eccentric anatomical genius, Jacobus Sylvius, the teacher of the still more celebrated Andreas Vesalius; but he does not seem to have transmitted any definite account, or even a suggestion, of their function. And here we come face to face with a specially interesting item of this strange, eventful history. Readers of ecclesiastical lore are, very necessarily, familiar with the name of Fra Paolo Sarpi (1552-1623), another restlessly inquiring genius, who, like his junior contemporary, the English Lord Chancellor Bacon, took for his province everything knowable, but with far more real success, as is well known to the skilled inquirer who is curious in these matters. We are assured by Johannes Leonicenus that the famous historian of the Council of Trent was thoroughly acquainted with the use, as well as position, of the intravenous valves; that they opened *like sluice-gates*, to permit the onward passage of the blood, and closed to prevent its return. This very representative authority also informs us that Sarpi communicated that knowledge to Fabricius ab Aquapendente—then Professor of Anatomy at Padua. The latter certainly described the valves—and figured them beautifully—in his great folio work on human anatomy; but he does not seem to have clearly grasped the physiological function which seems to stand out in so vivid relief from his "pictured page." Indeed, he refers to "flux and reflux of the blood" in a way which readily recalls the old, old Euripus problem and necessarily suggests that the latter still remained unsolved. However there are good reasons for believing that in the riper years of his life Fra Paolo would not have been very openly communicative in the matter of any of his more specialized secrets; the radicalism of his opinions upon many important subjects, and his candor in the expression of the same, had, again and again, brought him into very serious trouble with the Church.

Whether the statement that Fabricius ab Aquapendente owed his first knowledge of the valves of the veins to Fra Paolo Sarpi be accurately true or otherwise, the fact is undoubted that he was acquainted with their structure, and was particularly fond of demonstrating their presence and arrangements in the course of his anatomical lectures. The fame of the University of Padua, "Nursery of Arts," was then in its zenith; that of its school of anatomy far overtopped the reputation of all others of the kind then existing. William Harvey proceeded to Padua for the purpose of studying the structure of the human body under the guidance of the greatest living exponent of its mysteries. He attained the Doctorate of that University in 1602. He had seen the valves of the veins demonstrated by his master. He returned to England to practise his profession. Some time after his return, when taking a leisurely walk with an engineering friend, the discussion turned on the mechanics of the newly discovered valves of the veins —then the great and "very latest" novelty of biological information. Professor Fabricius had not given a clear account of the function of the interesting structures; Dr. Harvey professed himself unable to divine the private designs of nature in producing and placing them. But his engineering friend readily supplied the explanation; that, placed as they were, with their *free edges directed toward the heart*, the only possible function of the aggravating valves was to prevent regurgitation of the moving fluid in which they floated—the current of which, on account of the very presence of these structures, *must* flow *continuously toward the heart!* The missing—or doubtful—link in the circular current was forged at last! The Euripus riddle had found its Œdipus! But, horrible to relate, William Harvey had *discovered* simply—*nothing at all!* Such is reputation. Well may the Iagos cynicize!

But, on the other hand, the claims of William Harvey on the gratitude of posterity should never be disputed in this connection. The Italians of that date were by no means prone to cast their scientific and philosophic pearls before the intellectual swine of a semi-barbarous age—which surely accounts for the fact that this "discovery" had not become public property long before. Harvey published his epoch-making volume in 1628—not in England, be it specially noted—but in Germany! It contains a very elaborate account of the circulation, with all necessary demonstrative details. He had, however, been teaching those details for some nine years before. He had made a very full series of experiments for the purpose of completing the chain of demonstrative evidence. This required a good long period of time, by itself; and would almost account for the whole period of the delay in publication, as experimental methods and machinery went in those days. But pretty surely, his "prophetic soul" warned him of the explosive danger of a new doctrine so far-reaching in its association and consequences. For the appearance of his book had a truly thundering effect! Senior metropolitan physicians thenceforward refused to

meet him in consultation. (They very usually have done so, when possible, under corresponding circumstances. The consultant whose knowledge is far in advance of our own is one whose advice is oppressive to any one of us—especially when given with unquestionably honest and efficient candor, in presence of both patient and friends.) The publication of the immortal *De Motu Cordis* marked the ruin of William Harvey's consulting practice. Let Englishmen boast of their liberty of ("reformed," and thereby emancipated) thought and speech and action, and point to the treatment of Galileo by the authorities of the Inquisition—almost at the same date! If his medical contemporaries had been endowed with powers corresponding with those of the Inquisition, most assuredly William Harvey would not have escaped so lightly from the consequences of his "discovery" as did Galileo Galilei from those of *his* innovations!

I began the scrutiny of evidence corroborative of the assertion of an old-time acquaintance with the "general" or "systemic" circulation of the blood with definite reference to the testimony of Hippocrates (not omitting a glance at the probable attainments of the wisest of kings), the items of ancient testimony selected ended with Galen—but the continuity of the chain derived from the unquestioned authority of the latter cannot be disputed. Novel modes of inquiry, and views of education and intellectual subordination, blossomed with the expansion of the Renaissance; and the first mention of the available cloud of witnesses on the present topic was the contemporary of Michael Servetus, the roystering monk-physician whose name is so seldom associated by the average reader with either medicine, or physical science, or general education. Yet the fact is that François Rabelais was both a pioneer and an expert in each and all of those three departments. He was, indeed, not only a gifted, but a thoroughly earnest, representative product of the highest intellectual stratum of that most interestingly complex of all the recorded periods of the progress of human thought and scientific conquest. It is somewhat soothing to the reflective mind of the earnestly sympathetic student to find that the thorny pathway which has evermore been trodden by the foremost of the leading pioneers in the previously unexplored areas of the boundless forest of thought and discovery does not seem to have been beset in the case of Rabelais, with the average number of the poisoned pricks which made so bitterly painful the pilgrimages of others—and proved so horribly fatal in the case of Michael Servetus. But as to the coveted niche in the Temple of (scientific) Fame! In this super-educated generation of ours, who ever thinks of François Rabelais as one of the most important—and effective—of the pioneers of *modern education*, or of Michael Servetus as the rightful claimant to the credit of the discovery of the circulation of the blood? Echo (alone) answers!—at least in all English speaking communities. That such is not what should be will, I have considerable confidence in hoping, now be admitted by every reader who has taken the trouble of pursuing the story, and the argument, of this tortuously prolonged communication. Knowing, as I do, that it is only the members of the elect—even among the earnest—who have persisted in so doing, I appeal, without hesitation, to the charity which is the most characteristic endowment of all such, for forbearance in their final sentence on the writer who has, so long and so ruthlessly, taxed their patience. And with corresponding confidence I would appeal to the enlightened scientific citizens of the vastly greater—and infinitely more liberal—Geneva of the Western Hemisphere, to contribute as they best (most independently and effectually) can to the tardy justice which is surely due to the memory of one of the most earnest and single-minded votaries of science; one of the most stainless practitioners of the one profession which was practised and consecrated by the Saviour of mankind himself, during the troubled course of His earthly pilgrimage!

CANCER.

A SUGGESTION AS TO ITS CAUSE, AND ITS RELATION TO DISPLACEMENTS, FUNCTIONAL DISORDERS, AND THE NERVOUS SYSTEM.

By E. ATLEE, M.D.,

PHILADELPHIA, PA.

Neurasthenia is considered a contributory cause of displacement of the uterus. Contrary to this view, may it not be a *consequence* of this displacement; or, in other words, may not perfect health and functional integrity of pelvic viscera and floor depend upon perfect position of the uterus?

A displacement of the uterus may be due to a fall, strain, or other violence which produces an injury to its ligaments. To counterbalance the consequence of this accident, the muscular tissue will become tense, giving a temporary additional support to the uterus pending repair. The acquisition of this extra force in the abdominal and pelvic muscles, in response to nervous impulses, may be accompanied by a loss of force elsewhere, showing itself by functional disorders. Additional injuries to the ligament, with possibly a still further weakening of the support (due to ill-timed expenditure of force), finally result in sufficient malposition (irrespective of the *direction* or of the *degree* of the angle of deviation) to interfere with delicate nerve mechanism (by a bending, twisting, or stretching of the nerve, or by a pressure on the nerve structure). In consequence of this interference, nervous impulses can no longer be conveyed to or from the scene of the accident. The result may be: (1) that the tense muscles resume their normal tonicity; (2) that the nerve action of the rest of the nervous system returns to its normal equilibrium, with apparent perfect health and strength and maximum weight; (3) that the organ, still remaining displaced with a crippled nerve function, develops later a malignant growth.

Forms of cancer other than uterine may be the result of some local weakness dependent upon an initial pelvic injury. In those that might be called *sequential* forms of cancer we have in the incipient stage the history of concomitant poor or indifferent health.

The two causal factors of cancer probably are: (1) accidental injury; (2) ill-timed expenditure of force (subsequent to an internal injury) in muscular activity, ill-advised consumption of food, mental strain.

Excessive expenditure of force accounts for the following demonstrable (W. R. Williams, "Natural History of Cancer," pages 21, 66, 67) conditions: (1) excessive number of cancer cases found in temperate zones over that found in torrid zones; (2) excess of cancer found in civilized countries over that found in savage tribes; (3) excessive

amount of cancer in well-to-do localities where people are energetic, over that found in quarters where the inhabitants are not thrifty; (4) excessive cancer cases found, not within workhouses and asylums, where the inmates are taken care of, but among the self-supporting.

In the first stages of uterine cancer the uterus is (in most cases) freely movable and is frequently acknowledged to be out of normal position; while a dislocated uterus is held fixed. How can we account for the comparative freedom from cancer in those uteri which, besides being out of normal position, happen also to be fixed (by other than old adhesions, or extension of the disease)? Probably, in the incipient stage of uterine cancer, women previously subject to abnormal deliveries may go to full term and have easy labor, owing to normal tonicity of muscles. Because of the natural periodic increased weight of the organ, extra force is required monthly for an additional temporary support, creating still greater functional disorders at the period. After the menopause the extra supply of force is no longer periodically required, and the woman becomes stouter and stronger (other conditions being equal).

Many disorders now ascribed to causes other than displacements may in reality be the result of a lack of normal stimulus dependent upon a withdrawal of a part of the normal supply from its prescribed channel. The treatment of the resultant functional disorders should be rest, simplicity of diet, and happy mental attitude.

Neurologists and gynecologists, as well as other specialists, are prescribing the rest cure. Should this not prove entirely efficacious, then gynecological treatment might alleviate, or even cure, the symptoms.

If disorders, instead of being purely functional, have become organic, amelioration of symptoms would not immediately follow treatment, or even surgical intervention. If functional disorders are relieved by gynecological treatment, may not similar treatment cause a retrogression of the sequential forms of cancer?

In reference to the operative treatment of cancer, will not the excision of the area of the injured nerve insure the best results?

DIFFERENTIAL DIAGNOSIS OF LYMPHOMATA OF THE NECK.*

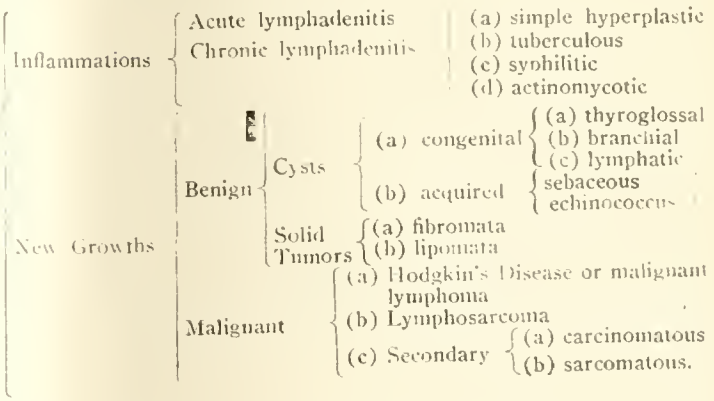
By EDWARD ADAMS, M.D.,

NEW YORK.

ASSOCIATE ATTENDING SURGEON HAR MORIAH HOSPITAL; INSTRUCTOR IN SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In order to make a correct diagnosis one must have a certain plan or scheme to follow, and in dealing with lymphomata of the neck the following division and subdivision of the subject seem most practical to my mind. First of all, lymphomata are divided into two great classes—inflammations and new growths.

I shall describe only very briefly the common difficulties met with in various regions in the neck. Around the ear there are several possible mistakes which must be avoided. Over the mastoid process there is a small lymphatic gland which is frequently



enlarged and often suggests at first sight mastoid disease. When the gland has broken down and becomes simply an abscess cavity the diagnosis may be difficult, but the absence of signs of middle ear disease and of edema of the upper and posterior walls of the external auditory meatus, combined with absence of constitutional disturbances which accompanies mastoid disease, usually leaves little doubt as to the diagnosis. In the parotid region it is sometimes very difficult to differentiate between an enlarged gland and a simple tumor of the parotid. The history of the case, the slow and increasing size, and the fact that the parotid gland is situated beneath the deep fascia should be the diagnostic points in favor of the parotid tumor. Cystic swellings of congenital origin are frequently met with, which at first simulate glandular abscesses, but their walls are smoother, the texture is more regular, there is no chain of smaller glands extending from them, and the mobility is much greater than would be found in an abscess of a similar size. Tumors in the sternocleidomastoid muscles are sometimes mistaken for glands, but the diagnosis can be made when the exact situation of the swelling can be determined and glandular tumors are not found within the substance of the muscle itself. In the newborn, in whom enlarged glands are rarely met with, sternocleidomastoid hematomata are occasionally seen.

In the submaxillary region, especially with cases of salivary calculus, the diagnosis at times is extremely difficult, inasmuch as the secondary lymphatic glands are usually enlarged as well. The affection of the salivary gland is usually accompanied by swelling along the side of the floor of the mouth, caused by inflammation of the salivary duct, which lies in such close relationship to the mucous membrane of the mouth that any swelling is readily apparent. Adenomata of the thyroid gland occasionally suggest glandular tumors. This occurs especially when the enlargement is restricted to the upper part of one lateral lobe or to an accessory thyroid. The attachment of the capsule of the thyroid to the pretracheal fascia, and hence to the trachea, causes the tumor to move distinctly on swallowing and this does not occur in the case of lymphatic glands, the fascia around which is attached to the carotid sheath rather than to the fascia of the trachea.

Acute lymphadenitis of the neck follows various infections of the teeth, mouth, gums, nares, tonsils,

*Read before the Harlem Medical Society, March 1, 1911.

etc., the superficial glands being chiefly affected. The diagnosis can be readily made by the history of the acute onset and pain on pressure, and the glands are so soft that they seem to fluctuate. They usually disappear in a few days, although suppuration frequently takes place.

Chronic lymphadenitis: A. *Simple hyperplastic lymphomata.* This term includes those lymphnodes that do not enlarge beyond the size of a bean to that of a hazelnut. This enlargement is produced by chemical or bacterial irritants entering by way of the lymphatic vessels from the periphery. The enlarged gland may undergo no change for years and show no tendency to suppurate or form adhesions. Caries of the teeth is the chief cause. A positive diagnosis can only be made by the microscope or bacteriological examination of the enlarged glands, because the initial stage of tuberculous glands differs very little clinically from that of simple hyperplastic lymphomata. B. *Tuberculous lymphomata.* The diagnosis of this condition can usually be made from the consideration of some of the following points: (a) The history of having existed for quite some time; (b) the size varying from that of a pea to an egg; (c) the fact that the glands are present in chains which consist of a number of glands of different sizes connected together; (d) some glands are freely movable while others are more or less fixed, the one caused by the tuberculous process being intracapsular, the other case where the gland has broken through the capsule, producing a periadenitis; (e) the presence of scars, showing that one or more of the glands have broken down, forming an abscess which has discharged through the skin, or has been opened by a small incision; (f) the tuberculous scars are usually characterized by irregular shape, never smooth, and are adherent to the underlying parts; (g) the glands are usually painless and there is little or no fever unless a general tuberculosis is present.

Syphilitic lymphomata: The diagnosis is made as follows: The primary stage should disclose an initial lesion of the face or the mouth, and the glands are large and painful. In the secondary stage the glands are small, freely movable, painless, never break down, and a single gland is involved, not a chain or group of glands. Tertiary stage: Gummata are extremely rare. They grow slowly, are painless, and have a firm, elastic consistency. When present they are at first not adherent to the skin, but when they break down and suppurate they become adherent to the skin, showing the typical syphilitic ulceration. In doubtful cases a Wassermann reaction will be of aid.

Actinomycotic lymphomata: The diagnosis in these cases can be made on the history of the slow growth and the tendency to form sinuses. The finding of the fungus in the discharge and tissues establishes the diagnosis beyond a doubt.

New growths—Congenital cysts: The thyroglossal tract sometimes forms cystic tumors instead of fistulæ. The chief diagnostic points are the location in the middle and lateral regions where congenital fistulæ occur and histologically the presence in the walls of the thyroglossal cysts of thyroid follicles. *Branchial cysts*: These are observed in the anterior region of the neck, in the middle line, or at the side. The diagnosis is very difficult and is made in doubtful cases by aspiration and examination of the contents in conjunction with the kind of epithelium found. In branchial cysts the lining is epithelial. *Lymphatic cysts*: These form large, thin walled sacs in the posterior triangle, and are frequently termed hydroceles of the neck. They may be single or multilocular, and consist of dilated lymph spaces. Formation of secondary cysts and a spontaneous tendency to disappear are the chief diagnostic points. The lining is endothelial in lymphatic cysts.

Acquired cysts: Sebaceous cysts of the neck. These can readily be diagnosed by their relation to the skin, their benign growth, and the fact that they remain stationary for years. *Echinococcus cysts of the neck*: These are rarely found in the neck, for out of a total of one hundred and ninety-six cases reported only two were found in the neck. The diagnosis is extremely difficult, and at times impossible, but an exploratory puncture may show the presence of hooklets in the cystic contents.

Fibromata of the neck: These may be either superficial or deep, and the diagnosis can easily be made on the history of the slow growth, by the consistency of the tumor, and the fact that they remain stationary for a considerable time. *Lipomata of the neck*: The diagnosis can usually be made upon the location of the tumor and the clinical picture of a diffuse as well as of subcutaneous circumscribed capsule being present and the fact that these tumors are usually single instead of multiple.

Malignant lymphomata of the neck, otherwise known as Hodgkin's disease, or pseudoleukemia: In the early stages it is extremely difficult to differentiate this condition from that of tuberculous lymphomata of the neck, but malignant lymphomata increase steadily in size, and sometimes attain the size of an orange. The diagnosis is made on the fact that they never break down nor invade the capsule, and do not form adhesions to the surrounding parts. Constitutional symptoms and glandular masses in other regions, as the axilla, inguinal region, etc., can also be made out. The blood shows very little change, and in doubtful cases a gland should be excised for diagnostic purposes. The slightly enlarged spleen in such cases points also to Hodgkin's disease.

Lymphosarcoma of the neck: Primary sarcoma of the lymphnodes is diagnosed clinically by the fact that it always occurs as a single tumor and rarely suppurates, spreads rapidly not only to the surrounding glands, but also to all the adjacent organs, and extends to all parts of the lymphatic system. Microscopically these glands show the structure of a true sarcoma.

Carcinomatous glands of the neck: These occur frequently when the primary focus is in the region of the lips, tongue, jaw, tonsil, etc. The left side of the neck receives metastases from the abdomen by way of the lymphatic duct, especially in carcinoma of the stomach. This is known as Virchow's sign. *Sarcomatus glands* are found as metastases, especially in angiosarcoma of the carotids, submaxillary, salivary glands, thyroid gland, etc. In both carcinomatous and sarcomatous glands they are at first freely movable, but later on become adherent to the surrounding parts. In conclusion I wish to state that at times it is extremely difficult to make a correct diagnosis clinically, and when possible a gland should be excised and examined by the microscope in order that the correct diagnosis may be ascertained.

300 Central Park West.

THE IMPORTANCE OF CORRECT HOSPITAL RECORDS.*

By ROBERT E. COUGHLIN, M.D.,

BROOKLYN, N. Y.

When the first hospital was instituted it is probable that history taking of cases treated was begun. At any rate, no matter how old an institution is, the keeping of records seems to have been a necessity, and a due appreciation of records kept was manifested in the early history of medical writing. Therefore by a process of evolution we should be in the best possible condition regarding this very important detail in medicine. Each medical staff representing a particular institution may use a little introspection to find out whether or not this evolution has brought out the best possible results. If perfection has been attained then no suggestions are necessary, but for the others who have found something wanting this paper is intended.

In the first place, let us decide who are benefited by hospital records. In the order of importance we should consider scientific medicine, the hospital, the attending staff, the interne staff, the patient, and the public at large.

One can easily understand how important to the scientific medical world is the careful recording of cases in large institutions where opportunities of all kinds are afforded for the consideration and grouping of large numbers of cases, so that conclusions may be drawn upon which the future treatment of similar cases may rest.

The hospital itself benefits in no small degree by such correct records, and as a rule hospital managers appreciate the importance of the subject by providing books, stationery, and everything to encourage the work. Many dollars have been saved to certain institutions where suits for damages were brought in court, and careful records showed that the officers were not at fault.

Carefully written hospital histories of cases are indispensable to a visiting hospital staff. In fact without such records of cases treated the attending staff fails in its duty in a most lamentable way. Not only are they as individuals realizing no benefit, but all other interests suffer and scientific medicine lags. With such men there can be no progress.

The interne staff is benefited in many ways that they do not as a rule fully realize. In the first place they come into close touch with the patient very much like a father confessor. The age and habits of the patient are gone into; in the family history, which is very important, any hereditary taint is jotted down as well as family traits in character and constitution; all previous history of disease and accident is recorded; the beginning of the illness under consideration, the signs and symptoms of the same illness or injury, all making a complete epitome. When this duty is performed properly it helps the interne to think clearly and accurately as well as inculcating the habit of careful observation, so necessary in a medical mind. It may be said that the interne who does not avail himself of this occasion to improve himself misses a golden opportunity which cannot be overestimated.

To the patient a history of his case is valuable in that a correct diagnosis of his condition may be reached in this way, not only at the time under consideration but at a subsequent admission to the hospital, when a change in the visiting staff may have occurred. It is certainly due to the patient that all means be taken to bring about a correct diagnosis of his condition.

To the public, who really support our hospitals, correct records of cases treated are deemed important, for how would the public know how the money donated by the people generally was used to the best advantage? They should know the cause of death where patients die under treatment, also the chances for the recovery of patients under treatment, and if the percentage of recoveries compares with that of other institutions under the same conditions. For instance, if the mortality rate be 2 per cent. in appendicitis cases operated upon in one hospital, where many cases of that disease are admitted, and 20 per cent. in another, where many or as many cases are admitted, then the people who are maintaining the latter hospital may ask the hospital managers why such a difference should exist. Other benefits to the public might be mentioned, but this one illustration will be sufficient to show that hospital records do benefit the public. Nothing will produce a feeling of distrust of hospitals in general, a feeling that we as physicians should not allow to occur, more inevitably than inaccurate or false hospital records.

A case has lately come to light where a physician was accused of falsifying the hospital records for the purpose of substantiating his claim in public that he had performed a certain operation a great many times, many or all of these operations occurring in a certain hospital. With the aid of an accomplice, it is said, he tampered with the hospital records to prove his contention. Expulsion from his county society by a unanimous vote was letting him off too easily. A man who will tamper with hospital records that were correctly written is as guilty or more so than he who would deliberately falsify the records in the beginning. In this case there is a great moral principle involved, and integrity is probably the greatest element to be considered in the making of hospital histories.

The question naturally comes up: How are we going to secure correct histories? In the first place the attending physician and the attending surgeon should see that each and every history has been properly written within twenty-four hours from the admission of the patient to the hospital.

A complete history should be demanded, including hereditary and previous history of illness and injury; also if the patient has ever been rejected or refused insurance by any insurance company or society. The slightest surgical condition should receive the same consideration as the serious condition requiring a major operation. A trivial ailment should be given as much attention in the matter of history taking as the most serious medical condition, for who has not seen a mild medical case become a very serious one after a few days in the hospital? The fact that they are admitted as hospital cases is insufficient reason to believe that something serious may be found after a careful examination.

Constructive and not destructive criticism should be employed and a little patting on the back will produce better results than a destructive critical analysis. Terseness along with clearness of diction is desirable, but too full a history is better than a short account of the case in which the essentials are not mentioned.

The visiting staff should encourage the taking of

*Read before the Norwegian Hospital Medical Staff, May 22, 1911.

histories by referring to the files and showing interest by offering suggestions, etc. In this way improvement in the system in vogue may be effected from time to time.

Complete and accurate pathological reports are indispensable in making a full history of any case. A hospital without a good pathological laboratory staff is very much handicapped. All reports should pass through two, or preferably three, hands before the final report is made in any given case. Mistakes are thereby made next to impossible. A hospital without a competent pathologist is at a standstill as regards its contribution to scientific medicine. Autopsy reports are invaluable to the working of a hospital along scientific lines. It seems as if some original work should be done in hospital pathological laboratories along with the regular routine of hospital pathological work.

In one of our most progressive hospitals the pathologist is paid a salary. In this way very efficient service is secured. Certainly it seems too much to expect a man to devote four or five hours daily to routine laboratory work without compensation. The time may come when the attending staffs of the different hospitals will have to create a fund for the expense of their laboratory, including the salary of the pathologist. It may mean pay a pathologist and be in advance or maintain no laboratory and remain at a standstill as regards scientific progress.

Complete *x*-ray reports should be made in suitable cases, and this means that every up-to-date hospital should have an *x*-ray machine. Correct pelvic measurements should be recorded in every obstetrical case and the use of the pelvimeter becomes a necessity.

No medical man attached to an institution should resort to any derogatory statement in the presence of assistants, internes, nurses, or others relative to history taking and hospital records in general or in particular. Such a destructive policy breeds indolence and indifference on the part of all concerned in the management of this detail of hospital work. In other words, their morale is gone. If an interne feels that the history he is taking is worthless or is bound to be considered so, he will not put his best into the same for obvious reasons. The same applies to his daily notes.

A condition which should not be allowed to exist is that in which the daily notes of both the interne and the nurse agree or tally even to composition. In such a case it is easy to see that one is doing the thinking and observing for the other.

Undoubtedly many or nearly all of the suggestions referred to are well known to physicians and surgeons composing different hospital staffs, but the reiteration of truisms may produce results where other means might not avail.

FRACTURE OF THE INFERIOR MAXILLA COMPLICATED BY COMPLETE DIVISION OF THE FACIAL ARTERY.

By WALTER C. CRAMP, M.D.,

NEW YORK.

ASSISTANT VISITING SURGEON, BELLEVUE HOSPITAL.

Fractures of the inferior maxilla are relatively frequent in occurrence and as a rule excite no unusual interest, the main consideration being the proper and efficient maintenance of the fragments in apposition in order to prevent deformity; and yet the following case is such a unique one with such an unusual complication that it seems to me to justify publication. In fact, a fairly careful and complete search into the literature pertaining to the subject fails to reveal a similar condition. I have never seen the subject mentioned in any of the textbooks on fractures and Dr. Lewis A. Stimson of New York, whose broad experience in dealing with fractures is unequaled, informs me that no such case has ever come to his attention, either by personal knowledge or by perusal of medical literature. The following case occurred on the Third Surgical Division of Bellevue Hospital in the service of Dr. Joseph D. Bryant, who saw the patient with me, and through whose kindness the report of the case is published.

D. S. was admitted to Bellevue Hospital on October 13, 1908, with the diagnosis of acute alcoholism and fracture of the lower jaw. He was a well-built man, thirty-eight years of age, accustomed to moderate inebriety, free from previous injuries and chronic diseases, and stated that while descending the elevated steps on the night of admission he fell about fifteen steps, striking on the left side of his face and left shoulder. Following the accident he was unconscious for a few moments and bled about a cup of blood from the mouth. On admission to the hospital there was nothing of unusual moment revealed by examination; the face was moderately swollen on the left side in the region of the lower jaw and there were contusions over the left shoulder and arm. Examination of the mouth revealed a fracture of the inferior maxilla on the left side about the junction of the body with the ramus, from which a slight amount of blood was escaping. During the night, however, there developed over the left side of the face and jaw a well marked tumor which extended well down in the neck, accompanied by a marked edematous condition reaching to the chest. There was also present some difficulty in swallowing. On account of repeated hemorrhages from the mouth, varying from one to four ounces, an operation was decided upon and the patient anesthetized. An incision parallel to the inferior maxilla was made over the prominence of the tumor on the left side, which corresponded with the submaxillary region. The tissues everywhere were infiltrated with blood and a large clot was evacuated in the neighborhood of the fracture, which proved to be a vertical one, with considerable displacement of fragments and running obliquely from behind forward and inward, leaving on the anterior fragment a thin, sharp projection of bone which had completely severed the facial artery as it turned over the jaw in front of the masseter muscle and had also slightly torn the vein. The bleeding was controlled by ligatures, the artery and vein being both tied, the projection of bone removed, the wound packed and partially closed by suture, no attempt being made to repair the fracture on account of the desperate condition of the patient which necessitated the performance of a high tracheotomy. The wounds healed kindly and the fracture was subsequently treated at the New York College of Dentistry.

This interesting case brings forward the fact that the facial, like other arteries situated close to bones, is susceptible to injury in certain fractures of the lower jaw and, though rarely injured, should not be lost sight of in dealing with them. This freedom from injury may possibly be explained by the absence of sharp projecting irregularities or spicula in fractures in this region.

349 West End Avenue.

NOTE ON A CASE OF ANEURYSM OF THE THORACIC AORTA TREATED BY ABRAMS' METHOD.

By M. L. TURNBULL, M.D.,
SAN FRANCISCO, CAL.

Dr. L. St. John Hely reported in the Medical Record, May 21, 1910, the remarkable and expeditious results attained in the treatment of a large aneurysm of the thoracic aorta which had perforated the chest wall by the method first advocated by Dr. Albert Abrams of San Francisco and fully detailed in his recent book on "spondylotherapy." I am informed by Dr. Abrams that, up to the present time of writing, he has a record of 39 cases in his own practice of thoracic and abdominal aneurysms which have been symptomatically cured within a few weeks by concussion treatment with absolutely no other adjuvant measures (not even rest) and that there was no break in the continuity of successful results. Some of his patients were seen after two or three years with absolutely no recurrence of symptoms.

The report of the following case I believe to be indicated, for the reason that we have heretofore regarded aneurysms of the aorta among the incurable diseases.

A. D., age 28 years. Sent to California by his physicians in Chicago for supposed pulmonary tuberculosis. Seven years ago contracted syphilis. Entered Dr. W. C. Voorsanger's service at the Mount Zion Hospital for dyspnea, pains in the chest, and a constant cough and expectoration which permitted him no sleep at night without the use of narcotics. Slight dysphonia. Veins of the neck very prominent and dilated. Slight tracheal tugging. Pronounced dulness on percussion of the upper chest corresponding to the arch of the aorta, which measures 6 cm. in diameter. Systolic murmur over aorta propagated toward the left shoulder. Palpation reveals a diastolic shock over the region corresponding to the orifice of the pulmonary artery. A skiagraph shows an immense aneurysm of the thoracic aorta chiefly implicating the arch. Examination of the sputa negative. A vigorous course of inunctions was without effect on the symptoms. At this time the patient presented an anemic appearance and his weight was 118 pounds.

Treatment by concussion daily of the seventh cervical spine was commenced on April 26, 1911. After the first séance of concussion lasting ten minutes the systolic murmur over the aorta almost disappeared. On April 29 the aneurysmal dulness measured transversely 2.6 cm. May 1 the aneurysm measured 2 cm. and the patient's weight was 123 pounds. May 3, 1911, there was absolutely no dulness over the site of the aneurysm, the pains in the chest were gone, expectoration was reduced about 50 per cent., but the cough continued with less frequency and severity.

On July 1 the patient's weight was 135 pounds. He had absolutely no symptom beyond an occasional slight cough, which might be attributed to a nasopharyngeal catarrh.

Workingmen's Endowments.—The German Reichstag is actively debating schemes for the mutual endowment of workers. The main topic will be the measure consolidating the present compulsory insurance laws. A report in several volumes, containing over 2,000 pages, has been prepared by the committee appointed to investigate the matter.

Remote Results, Functional and Obstetrical, of Pubiotomy.—Albert Peralta Ramos has made a study of the cases of pubiotomy done at the hospital at Canton (South America), from 1904 to date. This includes 18 cases from which an answer has been received to the questions asked, a considerable number having been lost sight of by removals, etc. These 18 cases included 13 multiparæ, and 5 primiparæ. The time since operation is from seven months to five years. Histories of these cases are given. All of these patients expressed themselves as satisfied by the remote result of the operation, all being able to do their work and to walk naturally. None of them had any trouble in walking after the first few days out of bed. In three cases there was slight pain in the leg of the operated side for a short time. In one case there was a slight sciatic neuritis from pressure of the sacroiliac synchondrosis. There were no bladder troubles. As to whether there was a permanent widening of the pelvis after the operation: there were three osseous unions, three fibrous unions in process of ossification, and seven completely fibrous unions; one case was without union after one year and nine months, having formed a pseudoarthrosis. Thus we see that fibrous union predominates. In literature the author has found records of 30 cases of labor after pubiotomy. Of these 18 labors terminated spontaneously or by version or extraction with living children; in 12 a fresh pubiotomy had to be done or a cesarean section performed. Of the author's cases eight had labors after the operation; 7 terminated spontaneously, and one required a renewed operation. The conclusions offered are that functional impotence does not generally result from pubiotomy; that fibrous union is the rule; and that the normal diameters are restored, any permanent dilatation being the result of a bad union of the wound.—*Annales de Gynécologie et d'Obstetriques.*

Intoxication with Nitroglycerine Among Operatives in the Powder Factory at Liri.—Duilio Balestra has made examinations of a considerable number of operatives in the powder factory at Liri, who were suffering from intoxication from nitroglycerine used in the process of manufacture of solanite and balistite. The symptoms produced were headache, vertigo, ringing in the ears, amblyopia, nausea, etc. In the process nitration, separation, and washing are used, in all of which the materials are agitated, so that vapor is evaporated and inhaled by the workmen. It may also be imbibed through the skin. An examination of the blood of the operatives was made, as well as a complete physical examination. The symptoms observed were due to nitroglycerine circulating in the blood; there were found characteristic spectra of methemoglobin. Brief histories of twelve cases were given. The author was surprised at the small number of cases affected by the drug. It was noted by the laborers that the use of alcohol made the symptoms more likely to occur, and they avoided the use of alcoholic drinks. In acute poisoning there is a lowering of arterial tension, by dilatation of the small arteries, due to weakening and paralysis of the vessel walls; the pulse is large and soft; this causes changes in the cerebral circulation. In chronic cases there were slow pulse, almost bradycardia, and a hard radial pulse. This would suggest that there is an action in the system such as to neutralize the phenomena of vasodilatation. The most important symptom is headache, of a dull type, in the frontal and occipital regions. The alterations in the reflexes were not notable. Gastrointestinal symptoms were next in order of frequency; they were pain in the abdomen and meteorism due to a slight paresis of the muscular coats of the intestine. In two individuals there was a slight diminution of hemoglobin. No other appreciable changes were found in any of the cases. There were permanent alterations in none of the organs.—*Giornale di Medecina Militare.*

THE PATIENT OF MODERATE MEANS.

A STRIKING anomaly in medical practice, which has frequently furnished a text for comment by both physicians and laymen, has been the fact that, whereas the wealthy and the poor are able to command the most expert medical service, this privilege is apparently denied to the person of moderate means. This fact is brought into sharp relief when the case is an obscure one, requiring the services of many expert diagnosticians and laboratory investigators. In his delightful book entitled "One Hundred Surgical Problems" James G. Mumford, in discussing a case of this kind, vividly presents the situation regarding this class of patients in the following words:

"I have long held that our present method of dealing with persons of small means who are the subjects of obscure illness is unsatisfactory. Patients of the poorest class can secure expert examination and advice by entering a large hospital, where they have the benefit of numerous consultations with different experts. Much in the same way wealthy persons can employ the services of numerous experts to determine their ailments while they pay large fees for such information. Persons of limited means, however, must not expect to be treated as paupers, nor can they afford numerous expert opinions. Such was the case with Mr. M. He lay in bed many months without a satisfactory investigation of his case. His family physician, although a man of excellent attainments, was unable to provide several expert opinions, and the patient suffered from that fact.....I believe the time will come when it will be possible for groups of physicians, acting in concert, to investigate and treat diseases of persons in small circumstances and at moderate fees. As the situation stands at present most of those unfortunate patients are cut off from the best of modern scientific medicine."

This is a situation the reality of which must impress every practitioner. The remedy suggested by Dr. Mumford is an admirable one. Surely in every large community there will be found a number of men engaged in special lines of practice who would be willing to cooperate for the benefit of the patient of moderate means, without loss to themselves or hardship to the patient. Such cooperation would be particularly feasible in the case of physicians having offices in the same building.

PSYCHOGENOUS AFFECTIONS WHICH ARE NOT HYSTERICAL.

NOTHING is more needed at the present day than a monograph on psychogenous affections in subjects free from hysterical stigmata who do not present symptoms of major hysteria. Such conditions are of daily occurrence. Nothing is more common than psychic and somatic disturbances following violent outbursts of temper or thwarting of the will in vigorous women; lovesickness, with all that it implies, is seldom mentioned in textbooks, nor is jealousy. Monographs exist on these subjects but they are among the curiosities of medical literature. Sudden grief or other psychic trauma may play pranks with the soundest individuals, yet there may be no suspicion of hysteria and no syndrome of nerve exhaustion. The manifestations may consist in the simulation of organic disease, especially phthisis—rapid loss of weight, night sweats, a hacking cough, etc. This picture may shift suddenly to something quite different, but after a variable interval the original state of good health returns spontaneously. In order to study the literature of such phenomena it is necessary to read works of a psychophysiological bent, for we do not find them among clinical writings.

At the recent annual meeting of the Deutsches Verein für Psychiatrie (*Deutsche medizinische Wochenschrift,* August 3) Bonhöffer takes up this subject, but unfortunately he deals with psychic psychogenous affections only and the more interesting somatic disorders are not discussed. He considers merely all psychic affections on a degenerative basis which have no known organic substratum and which stop short of the major psychoses. He does not mention the phenomena usually considered under psychasthenia (phobias, obsession, fixed ideas), and his object is evidently to separate from hysteria many severe psychic psychogenous affections which have usually been confounded therewith. Some of these are epileptic twilight states, hallucinations of prisoners, paranoid states in degenerates, poriomania, etc. Elsewhere he speaks of depressive states in constitutionally depressed individuals, which result from distressing experiences and may develop into paranoid states.

PRECOCIOUS TERTIARY LESIONS FOLLOWING TREATMENT OF EARLY SYPHILIS BY 606.

SINCE tertiary lesions occur in a relatively small proportion of syphilis cases and then as a rule in connection with some accessory factor, they have not been looked upon as an integral part of the disease. Were they such any remedy which tends to shorten the course of the disease might be expected to cause an early appearance of gummatous lesions which ought naturally to pursue a mild course. Neither mercurials nor iodides, however, have ever been accused of hastening the development of syphilis in this manner. On the contrary, their early and persistent use in the secondary period has usually been regarded as the best guar-

antee against the appearance of tertiary lesions, the latter being regarded in the light of occasional and preventable sequelæ. From another viewpoint malignant syphilis is characterized in part by early supervention of tertiary lesions, sometimes in spite even of vigorous and timely treatment.

It is therefore a matter of surprise to find that Wehner of Berlin has placed on record a series of cases in which the early use of Ehrlich's remedy appeared to precipitate the development of tertiary lesions (*Münchener medizinische Wochenschrift*, August 8). The first patient, a young man, who had relapsing papules in the throat after a course of inunctions, received one intramuscular injection of 606 which caused the papules to subside rapidly. Three months later a gumma appeared in the tongue. The patient was placed on mixed treatment and promptly recovered. He was next given a second injection of salvarsan and has since remained well. The other cases were similar and the author finds such material in literature by no means rare.

Wehner believes that arsenobenzol, usually so efficacious against tertiary lesions, is, nevertheless, somehow able to hasten the evolution of the latter in exceptional cases. He suggests that in destroying the bulk of the spirochetes it may reach a few of the latter in such minute quantities as to irritate and activate them. He would, therefore, always employ mercurials with salvarsan, whether jointly or alternately. The latter should also be given in a second injection if there is any suspicion of tertiary accidents.

BACCELLI'S PHENOL TREATMENT OF TETANUS.

A BRIEF abstract of Prof. Baccelli's article on the results of the application of his carbolic-acid method of treating tetanus in nearly two hundred cases appeared in a recent number of the MEDICAL RECORD. The percentage of recoveries is startling. Some years after the introduction of the antitoxin treatment an analysis of a hundred cases or thereabout showed a mortality of over one-half; but the objections were made that many cases included were mild and would have ended in recovery under any plan of treatment, while many cases had never been reported; and further that serotherapy could not be looked upon as essentially and inevitably curative when merely superadded to the symptomatic treatment already in vogue for years. The prophylactic value of the serum, on the other hand, has hardly been seriously questioned.

The combined fatalities under Baccelli's method are only a little over 17 per cent., a remarkable showing from any point of view. There may be some objection to the validity of the conclusions suggested by these figures. It may be argued that in tetanus one is morally bound to use antitoxin and sedatives, and as a matter of fact it is nowhere claimed that the patients recovered on phenol injections alone, while it is sometimes stated expressly that serum was also employed. It will naturally be charged that scores, perhaps hundreds, of fatalities have been suppressed for some alleged reason, or were never placed on record. Baccelli has anticipated this criticism by the very careful classification of his material into mild, medium, severe, and foudroyant cases.

It is usually assumed that between 10 and 20 per cent. of all cases of tetanus have some tendency to spontaneous recovery. These cases are classed by Baccelli under mild and medium and make up a little over 20 per cent. of all his material. None of this series was lost. At the other extreme are the fulminating cases, none of which was saved with the exception of one recovery after intraspinal injections of phenol. To judge of the value of the treatment we must depend on the outcome in the severe and very severe cases. Of the latter eleven are eliminated by Baccelli because the phenol was not employed in sufficient dosage. The net material comprises one hundred and twenty-one cases, of which ninety-four are termed severe and twenty-seven very severe. Of this number but seven patients died, a mortality of less than 6 per cent. for a type of disease in which there is absolutely no tendency to spontaneous recovery, and upon which even antitoxin and the most heroic sedative treatment have made but little impression. For the present the surgeon can hardly refuse to employ Baccelli's method by the full technique, in addition to all other remedies of proved value in every case of severe tetanus. We should then, before long, be in position to answer the question "is tetanus conquered?"

THE MERITS OF A RELATIVELY LOW PROTEIN DIET.

A DISCUSSION dealing with the merits of a relatively low protein diet took place at the recent meeting of the British Medical Association at Birmingham. Among others who spoke was Professor Chittenden of Yale. Dr. Chalmers Watson of Edinburgh in reviewing Chittenden's address said, in part, that at the present time the great desideratum was not the mere reassertion of views previously regarded as established, but the attainment of new facts, the critical analysis of the same, and the exercise of due caution in applying the results of experimental data to the conditions obtaining in everyday practice. The speaker's clinical experience led him to accept the conclusions of Chittenden that the ordinary conceptions of the protein requirements in man were exaggerated. However, no general statement could be laid down for universal application, for in the case of tuberculous individuals a somewhat higher standard of protein was necessary, gouty people on the contrary required less protein. Even in such cases caution was needful with regard to the indiscriminate giving up of the animal portion of the dietary. Too large amounts of farinaceous foods were not indicated for the gouty. Watson referred to his experimental work carried on during the past eight years in the physiological laboratory of the University of Edinburgh, in which his observations dealt not only with the absolute quantity, but also with the source and nature of the protein food given. It was pointed out that there had been a great increase in the consumption of animal food during the past fifty years, the increase in Great Britain having been from 3 pounds per head per annum to

50 pounds. A too exclusive protein diet interfered with the proper growth and development of an animal. C. B. Paul had shown that a meat diet diminished the size of the reproductive organs, and other organs, notably the mammary gland, suffered in a similar way, while the thyroid gland was hypertrophied. On the whole, therefore, Watson agreed with the main contentions of Chittenden, that a reduction in the protein content would increase the power of resistance in a small mammal. There are those, of course, who carry this teaching too far by advocating a diet entirely free from meat. It would seem to have been proven in a satisfactory manner that the majority of people eat more meat than they need, but it has not been proven that no meat is required by the human animal. A mixed diet is best adapted to the majority of people and some need less protein content than others. A person usually thinks he knows the diet best suited to him, but his conclusions are very apt to be based upon his appetite, and unbiassed medical advice on the matter is indicated, though even this, for obvious reasons, is often difficult to get. The old saying still holds good to some extent, that what is one man's meat is another man's poison.

Muscular Atrophy of Traumatic Origin.

From the number of neuroses which are constantly coming to light one might conclude with justice that the nervous system of mankind is still in the active evolutionary period, a conclusion also warranted by many other phenomena—for example the relative recency of paresis and locomotor ataxia in comparison with the much greater antiquity of syphilis. To ascribe some of these phenomena to retrogression is to introduce no new element, since many evolutionary changes are virtually defects, and a given change may represent an asset or deficit according to the point of view. Quite recently several cases of limited muscular atrophy following trauma have been placed on record, and are generally regarded as new in type. They also differ among themselves. Schuster's case was free from other trophic disturbances and from vasomotor complications and because of fibrillary twitchings and increase of tendon reflex on the affected side he ascribed the condition to a spinal lesion. The atrophy was transitory, but returned many years later. A different type was described by Cassirer before the Berlin Society for Psychiatry and Nervous Diseases last May (*Berliner klinische Wochenschrift*, July 31), and similar cases have been reported by Sudeck. A man stumbled and threw all his weight violently on his left foot. This became painful and the patient had to walk with two canes, finally taking to his bed. There was no external injury. The entire musculature of the extremity atrophied, including some focal rarefaction of the bones, and various vasomotor and trophic symptoms came in evidence. The traumatic nature was manifested in the fact that recovery slowly set in after prolonged rest, although a high degree of atrophy persisted. The injury appeared to have affected the trophic function of the nerves, which is known to be amenable to peripheral influences. In the discussion of these cases the point was made that ordinary progressive muscular atrophy might begin locally from traumatism and then become generalized, but in the cases cited there was no progressive involvement.

Function of the Spleen.

The function of the spleen is practically unknown, although the organ has been generally believed to be connected with the genesis and destruction of the erythrocytes. The fact that the organ can be removed without any apparent injury to the economy has furnished a stumbling block to investigators. It was known that the organ stood in some relationship to digestion, since it enlarges after a meal; that the passage of its blood through the liver must have some meaning, and finally, as hinted above, that it appeared to be a blood-making as well as a hemolytic organ; but no real correlation could be deduced from these facts. Ascher (*Deutsche medizinische Wochenschrift*, July 6) has invoked biochemistry to shed light on the nature of the splenic functions. It has long been known that the organ is rich in iron, a substance essential to life through its connection with oxidation. Experiments tend to show that the organ is essential for iron metabolism. A splenectomized man excretes more iron than his intact control. The spleen clearly takes up and retains iron set free during metabolic processes, *i.e.* as a result of cytolysis. In splenectomized animals the number of red corpuscles is decreased, provided the food is poor in iron. The newly born child is richer in iron than the adult, so that milk, its natural food, may be poor in iron without detriment to it. Many similar facts have accumulated which tend to support Ascher's theory.

News of the Week.

Cholera Spreads.—A despatch from Milan, Italy, dated August 31, states that cholera is spreading and that its ravages have become alarming. Premier Giolitti is quoted as saying that 800 towns and villages are stricken. Newspapers declare that three-fourths of the population of Leghorn, where over 800 cases have been reported since June 7, have fled. The epidemic is severe in Liguria and the Genoese Riviera. Conditions in Calabria and Sicily are represented as serious. The peasantry are convinced that the Government is poisoning the wells and are preparing to wreak vengeance on the officials. The villagers of Gricola have murdered the tax collector, holding him responsible for the cholera outbreak in that locality. Reports from Constantinople are likewise disheartening. Returns up to August 31 showed 75 cases and 31 deaths from the disease in Constantinople. There has been a heavy mortality in the Turkish garrison and at the Albanian camps. At Uskup, in the vilayet of Kossovo, there is an average of 50 cases daily, while at Monistir, in Macedonia, the disease is equally virulent. As a precautionary measure against the spread of infection all the old houses in the ghetto district of Constantinople have been ordered burned.

Killed by Automobiles.—The National Highways Protective Society reports that in the State of New York for the past three months 74 persons were killed and 522 injured by automobiles, while during the same period of 1910 there were 51 killed and 222 injured. This is an increase of more than 45 per cent. in the number killed. During the month of August 26 persons were killed by vehicles in the streets of New York City and more than 200 seriously injured: in the State outside the city 24 persons were killed and 192 injured. The report states that deaths and injuries

by taxicabs have decreased from 33 per cent. to 1 per cent. and that most of the accidents were caused by careless owners or private chauffeurs.

New Pavilion for Measles.—The Department of Health has closed a contract for the erection of a pavilion, at a cost of over two hundred thousand dollars, for the isolation of measles on the grounds of the Willard Parker Hospital at the foot of East Sixteenth street.

Gifts to Charity.—Under the will of Mitchell Valentine the Presbyterian and Hahnemann Hospitals are the largest beneficiaries. Each of these institutions will receive a percentage of the estate amounting to about $1,146,826. The Presbyterian Hospital gift is to be known as the "Isaac E. Valentine Memorial Fund," and that to the Hahnemann Hospital as the "Stephen Valentine Memorial Fund." The Peabody Home receives $100,000, which is to be known as the "Alexander Valentine Fund."

The contest filed against the will of the late Walter E. Duryea has been withdrawn and the will admitted to probate, thus making possible a distribution of the funds bequeathed to philanthropic institutions. Among these bequests are: Nassau Hospital, Mineola, L. I., $25,000 outright and $75,000 upon the death of the testator's sister; Children's Home, Mineola, $5,000; Roosevelt Hospital, $15,000, to establish three memorial beds in the men's, women's, and children's wards; Mountainside Hospital, Montclair, N. J., $7,000; Montclair Convalescent and Fresh Air Home, $2,000.

Medical Society Purchases Journal.—The Iowa State Medical Society has authorized the purchase of the Iowa *Medical Journal* from Dr. Edward E. Dorr of Des Moines, its editor and proprietor. The official journal of the society will be under the editorial management of Dr. David S. Fairchild of Clinton.

Dr. Walter H. Fuchs and Dr. James B. Pritchard have been appointed members of the St. Louis Board of Health.

Dr. Charles Chassaignac has been appointed chairman of an executive committee of five to map out plans and carry forward the work of cleaning and sanitation, the need of which has become imperative in New Orleans, in cooperation with the city and health authorities.

Hospital for New London.—The Lawrence Free Hospital, made possible by the generous gift of $500,000 from the late Sebastian Duffy Lawrence, is rapidly nearing completion. The building is thoroughly modern in every respect and the equipment is said to be the finest in the State of Connecticut.

Seattle's New Hospital.—The new Providence Hospital of Seattle, which has cost approximately $1,000,0000, will be opened on September 23. The building contains five hundred rooms and accommodations for 300 patients.

Many Cases of Rabies.—Since January 1 the Health Department has examined 3,469 animals for rabies and 326 have been found to have the disease, while for the corresponding period of 1910 3,010 animals were examined and 172 cases of rabies found, thus showing an increase of 154 cases of rabies for this year. During the same period 279 people have received the Pasteur treatment in New York City and 479 from villages and small towns outside the city. During 1910 180 persons received the treatment in the city and 437 outside. In other words the Health Department has administered the Pasteur treatment to 899 people thus far this year as against 626 for the corresponding time in 1910.

Good Typhoid Record for Boston.—From January 1 to August 25 there have been only 225 cases of typhoid fever reported in the City of Boston, the smallest number for the corresponding period in any of the past five years. Since the second week in July 58 cases have been reported against 73, 103, 117, 125, and 160 in the preceding five years.

Less Typhoid Fever in New York.—For the week ending September 2 there were 121 cases reported, as against 158 for the same week last year; the average for this week is 125 cases. No new cases have developed at the Roman Catholic Asylum in the Bronx, where 31 cases were reported for the previous week. In the 56 days previous to September 2, 1,042 cases of typhoid fever have been reported to the Health Department from all boroughs, an increase of 241 cases over the same period of 1910.

Drs. L. Haynes Buxton and A. L. Blesh, members of the faculty of the Oklahoma University Medical School, have resigned. They allege as the reason for tendering their resignations that the school is governed by politicians and is being used to further political ends.

Dr. Fred H. Albee was recently appointed Professor of Orthopedic Surgery, Vermont Medical College.

To Placard Typhoid Fever in Philadelphia.—By order of Dr. Joseph S. Neff, Director of Public Health, all houses in Philadelphia containing cases of typhoid fever are hereafter to be placarded. It has been found that many cases result from infection through milk and also by importation through persons returning from vacations. Certain regulations with regard to the distribution of milk to houses conntaining cases of typhoid fever and the care of the used receptacles have been operative for some time, but the additional precaution of placarding is thought necessary to make other measures effective.

Professor Georges Dieulafoy died in Paris on August 18. He was one of the leading clinicians of France, a pupil and worthy successor of Trousseau. He was born in Toulouse in 1839, but passed all his medical life in Paris. He was professor of clinical medicine at the Faculté de Médecine, attending physician to the Hôtel Dieu, and member of the Académie de Médecine. His "Manuel de Pathologie Interne," of which sixteen editions have been published in France, has recently been translated into English.

Proposes a Health League.—Dr. G. B. Young, Health Commissioner of Chicago, is advocating a general citizens' health league in order to arouse public interest and enhance the efficiency of the health departments. Dr. Young would form such a league by uniting all minor organizations interested in public health work.

Colorado State Medical Society held its forty-first annual meeting at Steamboat Springs on August 15, 16, and 17, when the following officers were elected for the ensuing year: *President*, Dr. W. A. Jayne of Denver; *First Vice-President*, Dr. W. F. Senger of Pueblo; *Second Vice-President*, Dr. H. C. Dodge of Steamboat Springs; *Third Vice-President*, Dr. F. D. Dennis of Colorado Springs; *Fourth Vice-President*, Dr. B. D. Beshoar

of Trinidad; *Secretary*, Dr. Melville Black of Denver; *Treasurer*, Dr. George Miel of Denver.

The American Hospital Association.—The thirteenth annual conference of this association will be held at the Murray Hill Hotel, New York City, September 19, 20, 21, and 22, 1911, under the presidency of Dr. Warren L. Babcock of The Grace Hospital, Detroit. The secretary is Dr. J. N. E. Brown of Toronto, Ontario.

Health Work Among the Indians.—The Indian Bureau has inaugurated a plan by which it hopes to reduce the high mortality among the Indians. The reports show that the death rate is two and a half times as great among the Indians as among the white race, and that the average mortality for tuberculosis is 256 per cent. higher for Indians than for whites. The plan which the government has in view includes a house to house campaign by physicians, such as already has been started on the White Earth Reservation in Minnesota with apparently good results, open air sleeping at the Indian schools and sanatoriums, and moving picture shows demonstrating sanitary methods of living.

Smoke Nuisance Abated in New York.—Since the sanitary law in regard to the smoke nuisance was amended two years ago last July, the Department of Health has been instrumental in making more than 2,000 arrests for violation of this law. In nearly all the cases convictions were obtained and $6,000 has been collected in fines. The practically smokeless condition of New York has been secured, not by forbidding the use of soft coal, but by compelling the use of smoke consumers.

Dr. P. G. Spinelli, Professor of Gynecology at the University of Naples, was entertained at the Italian National Club on September 4 at a dinner at which 150 physicians from New York and Philadelphia were present. Dr. Spinelli is in this country studying the hospital conditions here.

Obituary Notes.—Dr. George Faulkner of Jamaica Plain, Mass., a graduate of Harvard Medical College in 1847, founder of the Faulkner Hospital in Jamaica Plain, member of the Medical Society of the State of Massachusetts, died at his home August 27, aged 92.

Dr. Walter Henry Maynard of New York, a graduate of New York University in 1898, died September 2.

Dr. John Duke Waller of Oak Park, Ill., a graduate of Rush Medical College, Chicago, 1883, died at his home August 22, aged 59.

Dr. Henry Arnold of Foster Center, R. I., a graduate of Vermont Medical College in 1880, member of the State Medical Society, died at his home August 24, aged 57.

Dr. Joseph Hensley of Oklahoma City, a graduate of Hahnemann Medical College and Hospital of Chicago in 1871, died at his home August 21, aged 70.

Dr. Thomas J. Jones of Des Moines, Ia., who graduated in medicine in 1884, died suddenly August 21, aged 57.

Dr. Charles T. Remme of St. Louis, Mo., a graduate of the Missouri Medical College, St. Louis, Mo., in 1877, died at his home August 25, aged 62.

Dr. Guy Clifford Powell of Peoria, Ill., a graduate of the Louisville Medical College, Ky., in 1898, died in Chicago, August 24, aged 43.

Dr. Jehiel T. Moore of Minneapolis, Minn., a graduate of McGill University, Montreal, Can., in 1874, died at his home August 19.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE NEW RADIUM INSTITUTE—RADIUM RESEARCH AND THERAPY—HOSPITAL REFORM AND THE INSURANCE BILL—CREMULE OR LOZENGE—OBITUARY.

London, August 18, 1911.

The Radium Institute is now an accomplished fact. This is the week of its opening for the reception of patients. You probably know that the idea of establishing it arose with King Edward, who mentioned it to Viscount Iveagh and Sir Ernest Cassell. They took up the matter at once and determined to build and equip such an institution, and they have carried out their determination. The building is in two parts, one for the necessitous, the other for paying patients. Everyone admitted must be sent by his usual attendant as suitable for the treatment. The amount of radium in the institute is estimated to be worth some £50,000. Probably no other establishment owns as much, and apart from that fact it is doubtful whether another radiotherapeutic establishment as proposed is in existence. On the ground floor there are both light and dark consulting rooms completely equipped. On the first floor are twelve rooms for treatment, each furnished with a couch and easy chair for the patient to occupy during each application. On the second floor are the laboratories with all up-to-date appliances for research, as well as for separating the radium from pitchblende and mounting it in various ways for use. Everything seems to bode well for the institute, and had King Edward lived to see the realization of his idea he might have been as surprised as he must have been pleased with the prospect of what may be achieved.

Radiology has engaged so many enthusiastic students that the literature of their researches is becoming almost oppressive in quantity. In all directions we are continuously offered new contributions. There were quite a number at the Birmingham meeting; perhaps the most important was by Professor Saubermann of Berlin, for he passed in review all the work on which is founded radium-therapy. He showed a number of tables which gave the results of absorption of the emanations by the fluids of the body, the effect on the tissues of the passage through them, and the disintegration products. A great deal of apparatus was also shown and the chairman expressed the sense of those present when he told the author they were much indebted to him for his valuable contribution and demonstration. Certainly, from his careful review, it appears that there is a very close connection between the radium emanation and the human organism—or rather one should say certain processes which take place in that organism. One of the most remarkable of these is the increase in the action of various ferments, as the peptic, lactic, diastatic, glycolytic, etc., as to each of these and other actions the professor gave the name of the worker who proved it and the date of his contribution. Blood-pressure, cardiac activity, secretion, etc., are also influenced; in fact, the entire field of metabolism. An increase of metabolism, secretion and excretion without depression, but rather with a nerve sedative and tonic effect, should go far to explain the therapy, and these effects would appear to be brought about by the disintegration products

—radium A, B, C, etc., which are left for a time in the tissues. It has been stated by several observers that in the pitchblende mines, where the air is highly radioactive, gout, rheumatism, and neuralgia are unknown. Observations have also been made as to the relation of winds to the relative activity. Similar differences have also been shown at various springs.

Dr. Sequeira gave an account of his experience at the London hospital, where he has treated over 400 cases with radium. In early cases of rodent ulcer a cure was to be obtained, but it could not be maintained that all these ulcers were amenable to the treatment. Involvement of cartilage and bone and the spread of the disease into the orbital cavity were likely to prove fatal. Several speakers testified that much good has been done with a small dosage of radium.

Dr. Armstrong of Buxton reported good results from the use of radium water by drinking, inhaling, or bathing, the two latter in conjunction with oxygen. In gout and rheumatism, various neuroses, and other conditions he had employed high dosage without any ill effect. He found an increase of excretion, of digestion, and, in fact, of metabolism generally.

Professor Farr of New Zealand related some interesting observations on the effect of radioactive water on fish. It was seen that ova placed close to the opening of certain artesian wells soon died, but not when placed at a considerable distance. Careful examination showed that the waters gave off a gas resembling the emanation from radium.

In the section of "Medical Sociology," whatever that may mean, the hospital administration and reform were discussed by non-medical contributors. Among these was Mr. Neville Chamberlain, who described the efforts that have been made to improve the out-patient department at the General Hospital. He had found that the medical staff were indisposed to select cases suited for this form of relief and to exclude those who should go to their private doctor or to a provident dispensary. Such an institution had been founded in Birmingham for the express purpose of improving the conditions of the out-patient departments of hospitals, and the appointments on the staff were open to all qualified men. Mr. Chamberlain favored the State aid of voluntary hospitals and some subsequent speakers agreed with him, but others were reluctant to allow the Government to claim a right to interfere.

Dr. L. Shaw of the General Hospital discussed hospital reform in relation to the Insurance Bill. He asserted that in future they would not need to provide checks to keep out unsuitable cases, but attractions to bring in suitable ones, so that the reformers might become either hospital enders or hospital menders. The first wanted to municipalize the hospitals, the others to continue the voluntary system. He held that insured persons would have to be dealt with at the hospitals only in consultation in cooperation with their insurance doctors. Therefore, hospitals could not admit them for such treatment as their insurance provided.

Sir J. Sawyer, who has at times evinced interest in pharmacological questions, proposes in The *Lancet* to make our lozenges more like sweetmeats. In shape he prefers a small globe, as I know others do. He suggests as a base for such a ball chocolate cream, which should be an encouragement to prescribers to employ their own formula. The fruit basis is pretty freely used, especially that of black currants, but there is room for chocolate. He states that this is made by triturating in a heated mortar Theobroma cacao (freed from lumps) with sugar (saccharose), adding water to make a paste, and flavoring. The cream is made by filling a small globular envelope of this mixture with a little milk mixed with sugar and evaporated to a paste. It is this latter paste which he recommends as a base for our prescriptions. Menthol, eucalyptus, borax, zinc sulphate, and many other drugs could be thus used, simply or in combination. To distinguish them from trochisci, he proposes the term "cremules," baptizing it "cremulæ." In a hurry he says a simple cremule could quickly be medicated by injecting into its center a minim or so of the drug needed with a hypodermic syringe. I suppose he has tried this, but the drug should not be one which would spoil the confection by taste or otherwise.

The death has occurred in London of Deputy Surgeon-General John Jones, M.D., late of the Indian Medical Service (retired since 1885). He served during the Mutiny, was with the field force after the capture of Delhi, and present at the actions of Narnone, Karkarala, and Mehndee; also at the capture of Bareilly and the operations in Oude, for which he was awarded the medal. He was M.R.C.S., 1853, M.D. St.And., 1856, M.R.C.P., 1860.

Another Deputy Surgeon-General, Robert Walter Clifton, died on the 16th inst. He qualified in 1857, and of course had retired for several years.

The death of Lieutenant Denis E. C. Pottinger, R.A.M.C., has taken place at Barlilly, India. He took the M.B., Ch.B. at the University of Edinburgh in 1907 and entered the Army Medical Service in the following year. He was only 30 years of age.

The death is also announced at Swatow, China, in his 46th year, of Dr. C. H. D. Morland, M.B. Durh., 1890, F.R.C.S. 1897.

Dr. John Sellars, who was M.O.H. and Coroner for Dundalk, has died in a private hospital in Dublin. Outside his professional work he was a familiar figure at the meetings of the National Rifle Association. For several years he was regarded as the Irish champion. He shot with the Irish eight for the Elcho Shield and won the Lord Lieutenant's prize. His last appearance at the ranges was at Bisley in July, 1910.

Dr. Charles William Low, M.O.H. for Stowmarket, has died there at the age of 50. He was a Bart's student, took his M.R.C.S. in 1884 and M.B. Durham, in 1886.

Dr. Ouston, F.R.C.S., Surgeon to the Newcastle Throat and Ear Hospital, though only 42 at his death (on the 1st), had established his position as a skilful specialist and was highly esteemed as a consultant by the profession in the North of England.

Influence of Altitude on the Treatment of Eczema in Infants.—A. B. Marfan lauds the favorable influence of altitude in the treatment of the severe generalized forms of eczema, when the itching and irritation are intense, and the child cannot sleep and loses appetite. If such a child be sent up into a mountainous place at an altitude of 1,000 to 1,500 meters, after a week or so the child will be able to sleep and eat, the eruption will become dry, and soon the little patient will be able to go home without having more than a transient return of his trouble. Since this disease is generally self-limited at about two years of age this treatment allows us to tide over until that favorable period has been reached—*Le Bulletin Médical.*

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

THE EPIDEMIC OF TYPHOID FEVER IN OTTAWA—REPORT OF COMMITTEE OF CONSERVATION OF CANADA—REPORT OF MEDICAL OFFICER OF HEALTH OF TORONTO—RATS IN MONTREAL AND IN MANITOBA—STATISTICS OF THE MONTREAL HEALTH DEPARTMENT'S ANNUAL REPORT—HEALTH CONDITIONS IN TORONTO—ACTIVITY OF THE ANTI-VACCINATIONISTS OF MONTREAL—COCAINE IN MONTREAL—HAMILTON HOSPITAL FOR THE INSANE DESTROYED BY FIRE—INSPECTION OF SCHOOL CHILDREN IN ONTARIO—THE METAL TRADES COUNCIL OF CANADA AND CHILDREN'S TEETH—DEATH OF DR. CHURCH OF MONTREAL.

Montreal, August 29, 1911.

The report on the epidemic of typhoid fever occurring in the city of Ottawa in the early spring of this year has been issued recently by the committee on public health of the Canadian Commission on Conservation. The immediate cause of the epidemic was the infection of the water supply by polluting matter, which was sucked through joints of the intake, an old aqueduct having been very improperly used as a sewer. The pollution of the water supply began at about the middle of December, and was mainly due to the unusual lowness of the river and to the freezing of the shallow places to the bottom, thus diverting the currents of polluting matter directly into the water supply. The pollution was preventable and was due in the first instance to carelessness, the conversion of an old aqueduct into a sewer, and, secondly, to the neglect of the municipal authorities to follow the recommendation of Mr. Hazen, on October 5, to treat the water supply with hypochlorite of lime. The continuance of the epidemic was due to various causes, the most conspicuous of which were the inefficiency of the hypochlorite to effectually sterilize the water until about February 22; to contact with persons ill of the disease; to preventable insanitary conditions; to defective plumbing. The lessons taught by the epidemic were that water is generally the chief mode by which typhoid fever is spread. The epidemic in Ottawa was plainly proven to be entirely due at first to a contaminated water supply. The investigation brought out the fact that in Ottawa there were filthy slums in which all the conditions favorable to the spread of typhoid fever were present, and lastly, that hypochlorite of lime is an efficient temporary purifying agent of water, but that in order to insure a pure water supply a reliable filtration system must be installed. The case of Ottawa, like those of Montreal and Toronto, and of many cities of the United States, only goes to show that so long as laxity is observed in the safeguarding of the water supply just so long will typhoid fever prevail. The Commission of Conservation of Canada has published a report during the past few weeks relating to the conservation of agricultural lands, fisheries, game, and minerals. From a perusal of the report it may be gathered that in the agricultural districts of Canada the domestic water supply is mainly procured from wells. That in a large number of instances these wells are unprotected and become polluted, the consequence being that typhoid fever is fairly prevalent in the rural parts of the Dominion.

As in the United States, so in Canada, coal mine accidents are reprehensibly frequent. The death rates per 1,000 men employed in the coal mines of Canada and the United States are greater than in any other country of the world for which accurate statistics are available. Furthermore, the report points out that fatalities in coal mines in the United States and Canada are on the increase, while Great Britain, Belgium, Russia, and France show a gradual decrease.

The report interprets the situation in this way: (1) The danger inherent in the work can never be eliminated, but might be brought down to a minimum, as indicated by the low, constant death rate in Belgium, Great Britain, and France. (2) Coal mine explosions occur very frequently in Canada and the United States. The causes for this loss of life are complex, and neither the operators nor the miners willingly submit to them. The committee recommends that careful investigation of conditions prevailing in Canadian coal mines should be undertaken with a view to remedying, at least, some of the abuses. Recently there has been a somewhat remarkable prevalence of rats in and about the docks of Montreal. The news, too, has come from Manitoba that there has been an invasion of rats on a large scale into Manitoba from the States to the south. This invasion has progressed steadily for some years past, the rats appearing further north each year and always in increasing numbers.

According to the annual report of the Montreal Health Department, issued recently, the death rate of the city increased slightly during last year, while there was a falling off in the number of births. The increase of the death rate, 0.37 per 1,000, is said to have been partly due to an epidemic of measles which occurred at the end of 1910 and to the large number of fatal cases of typhoid fever at the commencement of this year. The decrease of the birth rate amounted to 0.70 per 1,000 and the marriages were augmented at the rate of 0.56 per 1,000. It is shown in the report that the deaths for 1910 numbered 10,221, or 22.40 per 1,000, as compared with 22.08 per 1,000 of the previous year. The births numbered 16,616 or 36.45 per 1,000, as compared with 37.15 for the preceding year. As for marriages, the report shows that they numbered 4,386 or 9.62 per 1,000 inhabitants, as compared with 9.06 of the year before.

Dr. J. E. Laberge, head of the contagious disease department of the Montreal Board of Health, referring to the increase in the number of contagious diseases, stated that in his opinion this increase may be accounted for by the fact that physicians are complying more regularly with the provincial regulations. He also draws attention to the increasing number of cases of tuberculosis which occur in Montreal and thinks it is a matter that requires attention as it constitutes a public danger. The number of cases of tuberculosis registered at his department in 1907 was 919; in 1908, 1,000; in 1909 the registration was 1,114, and in 1910 the number had increased to 1,336. Dr. Charles Hastings, medical officer of health of Toronto, has handed in his report recently to the Board of Control. According to this report the following conditions are to be found to a lamentable extent: "High rents are being collected for small houses, dark rooms, tenement houses unfit for occupation; inadequate water supply; impaired and filthy yards and lands; sanitary conveniences which, by their position or for various reasons, have become a public nuisance, a menace to public health, a danger to public morals, and an offense to public decency." The report also stated that insanitary lodging houses

are increasing in Toronto. From ten to twenty men of foreign birth are often crowded into a small house. There are ninety-two tenement houses in Toronto, 447 people living in basements and cellars. The foreign colony is chiefly composed of Macedonions, Italians, and Jews. In view of the crusade against smallpox which has been initiated by the Provincial Board of Health of Quebec and by that of the city of Montreal, the anti-vaccinationists have caused to be distributed by thousands circulars advising against vaccination. The use of cocaine is on the increase in Montreal. According to the annual report of the Superintendent of Police of that city, one hundred and fifty arrests have been made since July on charges of using or selling the drug. Hamilton Hospital for the Insane was partially destroyed by fire on August 1. Eight of the inmates perished in the burning building.

The Ontario Medical Council passed the following resolution with regard to the inspection of schools at its recent annual meeting. That the council in the interests of school children recommend to the Minster of Education the advisability of taking a physical census of school children with a view to compare the health and physical condition of children in urban and rural districts, and in the meantime further recommend the training, as in Great Britain, of the students in model schools, normal schools, and faculties of education in such a knowledge of school hygiene as will enable them to recognize common defects and diseases of children.

The following resolution was passed by the Metal Trades Council at its meeting on July 25: Whereas, investigations of our schools have shown that children's teeth are in a deplorable condition of neglect and decay, and whereas the preservation of the teeth is essential to good health and good health essential to the enjoyment of life and, whereas, owing to the poverty or neglect of parents, large numbers of children suffer from an insufficiency of medical care and whereas money spent upon the conservation of public health is well invested, the prevention of disease being much cheaper than its care, and the maintenance of a higher standard of industrial efficiency more economical than permitting physical deterioration, to say little about the human side of the matter, be it resolved, that the Metal Trades Union Council of Toronto place itself on record as favoring free medical treatment as well as free medical inspection of school children, and as a step in this direction it call upon the Board of Education to establish free dental clinics in connection with the public schools, the children's teeth to be periodically examined and treated absolutely free of charge.

Dr. Howard M. Church of Montreal died recently, aged 39 years. The late Dr. Church had been demonstrator of anatomy at McGill University during the past ten years.

The Importance of Determining the Causes of Inebriety. B. T. Burley.
Professor Wertheim's Method for the Removal of Cancer Originating in the Uterine Cervix. H. T. Hutchins.
Suggestion in Medical Practice. G. G. Fernald.
A Report of Sixty Cases of Syphilis Treated with Salvarsan. J. H. Cunningham.

The Causes of Inebriety.—B. T. Burley states that inebriety almost always claims a neurotic legacy from its forebears. With this predisposition, the impulse toward intoxication arises from a desire to escape pain or to escape the exhaustion arising from illness, physical shock, lack of food, or the stress and worry of modern life. Another allied cause is the physical unrest which afflicts the neurotic and the idle. Another exciting cause is the influence of occupation. Salesmen become inebriates from the custom of furnishing dinners and wines to put through a trade. Among the psychological impulses leading to inebriety are imitation, the glorification of pleasure or abandon, and the impulse to increase individual sense to the detriment of common sense, *i.e.* the craving for intense states of consciousness. The history of intoxication shows that it has been exceedingly prevalent at times of rapid development, not only of the individual, but of the race.

Wertheim's Operation for Uterine Cancer.—H. T. Hutchins states that in cases of uterine cancer beginning in the cervix Wertheim's operation is the most satisfactory procedure which one has at present, and the surest. By it the most complete removal of cancer of the pelvis can be done and by its technique the attendant complications are most satisfactorily dealt with, the patient is given the greatest possible chance, and is left, in case a cure is not effected, in the most satisfactory postoperative condition.

Suggestion in Medical Practice.—G. G. Fernald states that the cases amenable to treatment by suggestion are obviously mental or those within the realm of neurology which have as a basis some pathogenic idea or association. But not all mental or psychiatric cases are to be included, only those which show a clear mentality and insight into their condition. There must be a desire for relief and the ability to cooperate. Cases of dementia, mania, confusional insanity, and senility are not among the psychotherapeutist's subjects. The melancholiacs have a strong desire for relief and crave reassurance, and those cases whose attention can be secured and held are good subjects, if of a sufficiently high order of intelligence to cooperate. The difficulty of fixing the attention is the greatest one encountered by the psychiatrist who wishes to employ suggestion in his treatment.

Salvarsan.—J. H. Cunningham, Jr., continues his article on the indications and contraindications for the use of this drug in the treatment of syphilis.

Forty-six Years of Medicine in New York. F. P. Foster.
The Value of Meat Broths. T. Darlington.
Recent Corrective Tenement Legislation. H. A. Smith.
Modern Vitalism. C. E. Woodruff.
Scab Formation in the Nose. W. P. Porcher.
Malpositions of the Liver. F. LeM. Hupp.
The Diagnosis of Benign Stenosis of the Pylorus and Duodenum. M. Gross.
A Case of Mixed Astigmatism Presenting Symptoms of Brain Tumor. A. Bray and M. Staller.

Medicine in New York.—F. P. Foster presents a retrospect of the development of medicine in New York City during the past forty-six years; reviewing three manifestations of professional activity—the hospitals, the medical schools, and the medical societies.

Value of Meat Broths.—T. Darlington refers to the power of meat broths in stimulating the appetite and the flow of gastric juice. They also contain an abundance of inorganic salts, which play a rôle in the protein changes of the body. Another abundant constituent is gelatin, which is readily digestible and is a proteid sparer, and at the same time does not form aromatic decomposition products.

Corrective Tenement Legislation.—H. A. Smith makes a plea for the abolition of the statute compelling the provision of a vent shaft in all tenement houses. This law has made no provision for venting toilets on "open stairs" such as are provided in the new model tenements, including those for tuberculous families, a number of

which tenements are nearing completion in New York City. The intercommunicating shafts are capable of breeding and transmitting disease and are not in harmony with the most advanced tenement construction. A resolution recently enacted by the New York Academy of Medicine stated, first, that the shaft should not be required, but that the open stairs afforded sufficient ventilation for the baths; second, that the periphery is better utilized for bedrooms than for baths; third, that the resolution be forwarded to departments having jurisdiction.

Modern Vitalism.—C. E. Woodruff concludes his essay on this subject in the following words: "It is quite evident, therefore, that the scientific discoveries of the last couple of decades, together with the failure of the theories of the prior half century, are having a profound influence in modifying all our conceptions of group activity, from the atom to that fond dream of philanthropists—the universal brotherhood of mankind. We now know that all are different kinds of life, and that each kind is merely the result of the cooperation of dependent dissimilars of a lower order practising mutual aid, often if not always through juxtaposition, like enzymes or corpuscles. As physicians, dealing with middle forms in the cell and body, we must take due notice thereof and govern ourselves accordingly."

Scab Formation in the Nose.—W. P. Porcher advances the theory that coagulation of the nasal secretions or scab formation occurs as a result of the inflammatory secretions of the lateral sinuses coming in contact with respired air. This assertion is evidenced by the fact that inflammatory secretion from a tracheotomy wound, or any other wound of the upper respiratory tract, coming in contact with the external air, will produce the same coagulation or scab formation. The natural inference from this is that one should first give free outlet to all pent-up secretions in the lateral sinuses and then administer that remedy which will maintain the fluidity of the nasal secretions, as well as correct the inflammatory conditions producing them. Potassium iodide, in gradually increasing doses, up to very large amounts, has been found to produce this result more than any other drug.

Malpositions of the Liver.—F. Le M. Hupp in discussing this subject reports a case of complete left transposition complicated with cholelithiasis, obstructive jaundice, and pregnancy. Operation was successful.

Benign Stenosis of Pylorus and Duodenum.—M. Gross states that this may be caused by tumors, adhesions, and angulation, and by hypertrophy or stenosis of the pylorus.

Mixed Astigmatism Simulating Brain Tumor.—A. Bray and M. Staller state that mixed astigmatism has been known to give rise to various reflex symptoms, headache, dizziness, actual vertigo, nervous irritability, gastric disturbances, twitching of the muscles of the face, insomnia, diplopia, and, in children, symptoms simulating petit mal have been observed as a result of this error of refraction. These symptoms may manifest themselves individually or they may appear in a group as a symptom-complex, simulating some serious lesion. The case that the authors report is one of mixed astigmatism that gave rise to a series of classical symptoms of a tumor of the brain, and only the ophthalmoscopic and retinoscopic examination revealed the nature of the condition of the suffering patient.

Decortication of the Lung for Old Empyemata.—By F. B. Lund. See MEDICAL RECORD, July 1, 1911, page 51.

Plastic Surgery of the Face.—J. S. Horsley states that the general underlying principles of plastic surgery of the face are, first, a careful mapping out of the work beforehand, then gentle handling of the tissues and flaps, and due consideration for their nutrition. The flaps should always be taken a little larger than seems necessary, especially in the case of burns. No dressing should be placed on these wounds unless there is considerable bleeding, and then a dry compress may be used for twenty-four hours. The raw surface should be dusted with boric acid powder, which forms a scab. If a dressing is used, the secretions from nose, mouth, or eyes will be absorbed and a septic poultice result. The suturing should be accurate, tight enough to approximate the surfaces closely, and should be removed as soon as possible.

Gradual Automatic Occlusion of Larger Blood-Vessels.—J. M. Neff reports the results of experiments made with a new method for gradual automatic occlusion of the larger blood-vessels at a single operation. The method consists in the use of aluminum clamps placed on the vessels and exercising pressure at once, with catgut wound around one of the clamps at its open end. An elastic rubber band is placed round both limbs of the clamp outside of the blades, which causes gradual compression of the vessel as the catgut is absorbed.

Sensibility of the Peritoneum.—J. F. Mitchell calls attention to the fact that there is a distinct and constant contrast between the parietal and visceral peritoneum. The parieal peritoneum is extremely sensitive to pain, but not to heat or cold, while the abdominal viscera possess no sense of pain; in other words, the visceral peritoneum and abdominal organs, innervated only by the vagus or sympathetic nerve, are not sensitive to pain, and painful abdominal sensations are transmitted only by the phrenic, the lower six intercostals, and the lumbar and sacral nerves which supply the parietal peritoneum.

Sanitary Record of the Maneuver Division.—J. R. Kean states that the sick-rate for the Maneuver Division up to July 1 was twenty per thousand, as compared with thirty-four per thousand for all troops in the United States for 1910. The largest cause for morbidity was venereal diseases (four per thousand), next came measles and mumps (three per thousand), the latter almost entirely among the newly arrived recruits.

Vegetable Diet in Psoriasis.—L. D. Bulkley believes that, while a strictly vegetarian diet is strongly advocated in psoriasis, and while under certain conditions it is quite possible for the lesions to disappear under its influence alone, with no other treatment, internal or external, it is to be clearly understood that this is not the only element of treatment to be considered, although undoubtedly the most important one. To obtain the best results there is need of constant medical supervision in order to secure the best working of the economy in all directions.

Cacodylate of Sodium in Pellagra.—J. O. Elrod pre-

sents the histories of four cases of pellagra cured or greatly improved by hypodermic injections of cacodylate of sodium.

Pathology of Joint Tuberculosis.—L. W. Ely rejects the theory that joint tuberculosis is of bony origin, and has come to the conclusion that bone tuberculosis is simply a question of red or lymphoid marrow. Wherever one finds this in bone there the bones will be found vulnerable to tuberculosis, and where the red marrow is not found one does not find unmixed tuberculosis. There is more red marrow in the bones of children than in those of adults, and hence more bone tuberculosis. Where primary tuberculosis of the shafts of the long bones has been met with it has been almost always or invariably only in the shafts of children's bones. The yellow marrow appears to be invulnerable unless a secondary infection is added.

Tonsil Instruments.—R. J. Tivnen describes the following instruments that he has devised: tonsil hemostat, tonsil sponge forceps, adenoid hemostat, tonsil-grasping forceps, and tonsil pillar separator.

Thyroid and Healing of Fractures.—R. L. Thompson and J. L. Swarts conclude that, in the limited amount of material which they have studied, the lack of thyroid tissue had no influence on the healing of fractures of the malar bone of the dog. They see at present no exact method of studying the results of complete parathyroid removal on the healing of fractures.

Nasal Splint.—M. D. Stevenson points out the disadvantages of the tampons and hard rubber and metal nasal splints for treatment of conditions in the nose, and recommends a strong, but soft and flexible, soft rubber hollow splint which can be adapted to the location and does not interfere with respiration.

Omental Cysts.—By S. Stillman. See MEDICAL RECORD, July 8, 1911, page 102.

Malta Fever in Southwest Texas.—T. L. Ferenbaugh reports four cases of continued fever of long duration occurring in individuals working at a goat camp. Agglutination tests made with the *Micrococcus melitensis* gave positive results.

Megacolon.—W. I. Terry. See MEDICAL RECORD, July 8, 1911, page 100.

Sodium Hydroxide for Sterilizing Instruments.—I. M. Heller points out the disadvantages of carbonate or bicarbonate of sodium solutions for boiling instruments for disinfecting purposes. Instruments, especially if plated, when boiled in such solution, come out covered with a white scum, are slippery and less quickly dried, and are likely to turn black, especially if they have any blood left on them. He recommends, instead, the use of sodium hydroxide in a 0.25 per cent. solution, which has none of these disadvantages.

Perforation of Pregnant Uterus.—K. F. Snyder reports the case of a patient who perforated her uterus in attempting to bring on an abortion. The abdomen was opened, the infected tract was drained, the patient recovered and was subsequently delivered of a healthy child.

Needle Holder.—E. Mingus describes an instrument which he has devised for the purpose of passing a needle where space is limited.

Microscopic Diagnosis of Rabies.—S. B. Moon describes a modification of the Van Gieson method for staining the characteristic nerve cell inclusions.

Ulcer of the Cornea.—E. L. Meierhof reports good results following the treatment of ulcers of the cornea by means of a solution of iodine, 1 grain; sodium iodide, 3 grains; and 1 ounce of water. Three drops of this solution were ordered to be instilled into the eye three or four times daily. No other treatment was used.

Housing and Town Planning. F. E. Fremantle.
The Hereditary Tendency toward Twin-Bearing, and the Influences Aiding in the Determination of Sex. J. Oliver.
The Discrimination of Color. F. W. Edridge-Green.
The Pathological Relationship Between the Appendix Cæci and the Uterine Adnexa. J. Birt. (With Notes of Operation by T. C. English.)
Meningitis Following Measles. C. A. Basker.
A Convenient Method to Test the Visual Fields for Color Without the Use of a Perimeter, for Application in Cases Suspected of Increased Intracranial Tension. T. A. Williams.
History of a Swallowed Pin. N. Balgarnier.
Eclampsia in Two Successive Pregnancies. J. H. Nixon.
Fracture of the Fifth Lumbar Vertebra. O. A. R. Berkeley.

Housing and Town Planning.—F. E. Fremantle concludes that the housing problem consists of defects both in quantity and quality of accommodation in relation to a changing standard of requirement. English conditions are considerably better than those in Scotland and Ireland or in foreign countries. There is marked improvement during the past 20 years. The poor will alwys live in the cheapest houses, and the oldest and poorest are essentially the cheapest. Wholesale removal of slums has been done much in the past and leaves little to be done in the future. Closure and demolition of single houses are means much used and of prime importance. New buildings for habitation by the laboring classes involve unnecessary waste of money, but may occasionally be necessary; they will then involve an increased rental. Town planning and the decentralization of industry in garden cities and villages offer a hopeful solution of the problem of congestion. Better administration, not legislation, is required. The main faults in the people's houses depend on their habits, characters, and intelligence. Practical education is the most important factor in improvement.

Twin Bearing and Sex Determination.—J. Oliver notes a proportion of twins of 1 in 104 confinements. The relationship of female to male births as a result of twin conceptions is two to one. This is a noteworthy phenomenon, since in European countries the total number of male births always exceeds that of female. The hereditary tendency to the production of twins is transmitted about equally by males and females. Experiment appears to favor the view that well fed females tend to produce a preponderance of female offspring and badly fed females a preponderance of male progeny.

Discrimination of Color.—F. W. Edridge-Green concludes that when special means are taken to have as pure a spectrum as possible, he can find no method which will enable him to distinguish the colors in a monochromatic region.

The Appendix and the Uterine Adnexa.—J. Birt reports a case the history of which and the pathological condition of the organs affected seemed to point to the appendix being the original source of infection, especially in view of the obvious evidence of recent inflammation in the appendix, and the fact that the left ovary and tube were normal. The organisms may have traveled directly along the appendiculo-ovarian ligament (Clado), or by some other more or less direct route.

Meningitis Following Measles.—C. A. Basker reports the occurrence of six cases of meningitis, probably of meningococcic origin, following an epidemic of measles.

Testing the Visual Fields for Color.—T. A. Williams describes a simple method of testing the visual field for color without the use of a perimeter.

History of a Swallowed Pin.—W. Balgarnier reports a case in which a pin which had probably been swallowed years previously, perforated the stomach and became embedded in the gastrohepatic omentum.

Eclampsia in Two Successive Pregnancies.—J. H. Nixon reports a case of this condition.

Fracture of the Fifth Lumbar Vertebra.—O. A. R. Berkeley-Hill reports a case of this condition, caused by a fall from a horse.

The Surgeon and the Industrial Worker. W. D. Spanton.
Afferent Fibers in Ventral Spinal Roots. L. J. Kidd.
Pancreatic Cyst: Rupture: Recovery. H. Walker.

On the Occurrence of an Intracellular Stage in the Development of Trypanosoma Lewisi in the Rat-Flea. E. A. Minchin and J. D. Thomson.

The Surgeon.—W. D. Spanton states that in the practice of the art of surgery, as well as in that of medicine, he has often been struck by the clear diagnosis which those who possess a good ear for music often make where others have failed for want of it. Others having mechanical gifts will improvise an apparatus, while another man is wondering how soon he will be able to get an appliance from an instrument maker. In the matter of drawing, again, one who has a good eye for it will usually make a neater, if not a better, operator than the one who has not; his lines will be more accurate, and the ends of his incisions will meet at the proper point, and his whole work will be more perfect. So, again, with the sense of touch; this requires a long education, but some never seem to acquire any delicacy of touch—their fingers are "all thumbs," and often they will endeavor to discover by force what can only be made out by the utmost gentleness in manipulation. For example, a movable kidney or other easily displaced tumor can often be made out only by a "surprise touch," and escapes at once from observation with any rough handling. A keen sense of touch is invaluable to the surgeon; a gynecologist especially is very much dependent upon it for success.

Afferent Fibers in Ventral Spinal Roots.—L. J. Kidd has already collected a large amount of evidence—surgical, experimental, histological, and embryological—which seems to lead to the conclusion that afferent fibers, in somes cases algetic, in others reflex, exist in the spinal ventral roots of man and many other vertebrates. In the author's opinion, one ought to divide ventral as well as dorsal roots in cases of intractable pain, except in the case of the third and fourth cervical ventral roots; here division would cause motor palsy of the diaphragm on the side of section; but, in connection with this, one must remember that unilateral phrenic palsy in man and laboratory animals does not usually cause danger to life.

Pancreatic Cyst.—H. Walker reports the case of a laborer, who following an act of unusual exertion experienced a severe pain in the epigastrium. This was accompanied by shock. Rupture of a gastric or duodenal ulcer was suspected, but the patient improved. Following a second attack a few days later the abdomen was opened and a pancreatic cyst was discovered. This had ruptured into the lesser peritoneal cavity. The fluid was withdrawn and the cyst drained. It was twelve weeks before the sinus closed and the patient recovered.

Trypanosoma Lewisi.—E. A. Minchin and J. D. Thomson, in studying the early phases of the developmental cycle through which the rat-trypanosome passes into the rat-flea, have found that the tryanosome penetrates into the cells of the epithelium lining the stomach (mid-gut) of the flea, and there goes through a process of multiplication.

Berliner klinsche Wochenschrift.

August 14, 1911.

Pyonephrosis and Prostatitis Actinomycotica.—Cohn gives a brief monographic account of this subject. A case is narrated in which the patient, fifteen years before consultation, had developed—after exposure to cold—pyuria with occasional hematuria and tenesmus vesicæ. The latter subjective symptom subsided in time but the urine retained its morphological alteration throughout. Four years ago tenesmus and dropwise incontinence set in. Patient had also become cachectic. The thorough examination which followed the first consulation revealed two possible sources of pus, to wit, the kidneys and prostate. The former organs were regarded as the main source of the pus. The condition was strongly suggestive of urogenital tuberculosis, but no tubercle bacilli were found. On the other hand cultures of all kinds revealed the presence of some form of actinomycetes, which was clearly not the same as the cause or causes of ordinary actinomycosis. The author emphasizes the fact that the term actinomycetosis—as distinct from actinomycosis in the older sense of that word—embodies the causation of an entire group of diseases; while the original actinomycosis is limited to the effects of the ray fungus proper, such as commonly attacks cattle, etc. The experience is regarded as sufficiently important to deserve an extended study; so that the present brief communication is only anticipatory.

Remote Results of Prostatectomy.—Casper has now done 54 prostatectomies which enable him to form conclusions as to final results. In 26 cases the normal functions of the bladder were fully maintained. In some of these the conditions before intervention were very unpromising. In but 3 cases did stricture of the posterior urethra develop as a consequence of operation. Cystitis before operation was almost constant (95 per cent.), but after operation 75 per cent. of patients were freed from their cystitis. Some time was often required for recovery and vigorous treatment was added. In regard to the working capacity of the kidneys after operation this is said to have been uniformly good, despite the original presence of certain renal lesions. Casper never operated until he had obtained favorable results as to renal activity as shown by the phloridzin test. Early experience showed him that diseased kidneys could cause postoperative mortality through suppression of their function. An unavoidable accident rarely present is lancinating pain in the legs with impaired gait, due evidently to operative injury of the hypogastric plexus. Another unusual result is prostatic hemorrhage which may fill the bladder with clots. These accidents tend to end fatally, and are to be avoided by doing a right-sided operation. Last but not least comes the question of relapse after prostatecomy. The author has no personal knowledge of this sequence.

Sugar Metabolism in Addison's Disease.—Schirokauer states that adrenalin hyperglycemia and glycosuria are now well known conditions, due to overproduction of adrenalin which seems to interfere with sugar combustion. Hence where there is a lessened production of adrenalin, such as would occur in Addison's disease we should expect to find the opposite syndrome. The finds in this direction, however, are by no means conclusive. The author has therefore made a special study of the sugar metabolism in a case of Addison's disease. It was necessary to perform venesection in order to test for the sugar percentages in the blood. These were of such amounts as to controvert the belief that there is any inevitable lessening of sugar oxidation in the disease in question. It is admitted that hypoglycemia may and often does occur under such circumstances; to such an extent in fact that its inevitableness has been taken for granted by many. It is better, however, to regard hypoglycemia as merely an occasional or inconsistent find in Addison's disease.

Münchener medizinische Wochenschrift.

August 15, 1911.

Puerperal Autoinfection.—Zangemeister states that there are many forms of mechanism for infection of any kind, all of which are practicable for puerperal autoinfection. These are as follows: 1. Inoculation proper, the germ introduced from without or within by a special trauma. This is self-explanatory. 2. The inoculation does not occur in the regular fashion, *i.e.* the germ is not introduced forthwith at the time of injury. Instead, an injury occurs, and latent bacteria improve the opportunity to inoculate the exposed surfaces. In such cases the germs preexist in the infected localities. 3. A wound is made—an aseptic wound—which becomes inoculated from within or without. 4. Germs enter the birth tract

of sufficient power to cause lesions and infections. These distinctions seem academic and inapplicable to practical teaching, but scientifically they are correct. And as long as such conditions are deducible *a priori*, so long the unraveling of the problem of autoinfection will be postponed. In plain language so many factors enter into the possible causation of puerperal sepsis that even an approximate solution of the problem is out of the question.

Effects of Passive Motion on the Circulation.—Veiel and Zahn, after referring to the incomplete knowledge at hand on this subject, give the results of their own experience. They conclude that passive rhythmic movements of the lower extremities cause at once an alteration of the distribution of blood. The supply of the latter in the legs is lessened. As a result the arteries in the arms are narrowed and the blood pours through them more rapidly. But in comparison with active exercise passive motion causes relatively little disturbance of the circulation. Of late years Büdingen has devised an apparatus for passive movements of the legs which is said to be of especial value in bedridden subjects, cardiacs and the like, in that it tends to prevent stagnation with its accompanying evils, such as marantic thrombosis.

Stasis Hemorrhage in the Skin and the Rumpel-Leede Phenomenon.—Strauch has examined 160 healthy subjects in regard to the existence of the Rumpel-Leede phenomenon (hemorrhage above the elbow joint after constriction of the upper arm). No less than 45 per cent. gave positive results, males predominating. To offset these figures 180 diseased subjects were examined. The disease is not stated and the inference is that ordinary hospital patients were tested. The percentage of positive results was 50. This increase can not be explained in any satisfactory way. Scarlatina may be eliminated outright, since positive results were obtained from an entire series of general diseases—erysipelas and diphtheria leading the list. In regard to the diagnostic bearing of this subject on the existence of scarlet fever, it can only be emphasized that absence of the phenomenon excludes the possibility of that affection. That is, in male patients, while not pathognomonic, the absence of the Rumpel sign should have much weight in excluding scarlatina.

Treatment of Gout.—Schmidt attempts to solve the problem of the curability of a disease of alien origin and nature, to wit, the gout. As a rule German writers on the latter affection draw almost wholly on English authorities. The old teaching was that alkalies are the rational treatment for this affection. Certain irregular practitioners in England rebelled against this view to such an extent that acids came to be the mode. Schmidt evidently subscribes to this point of view, for he advocates HCl in constant exhibition. He evidently believes that the sluggish metabolism of gout is evidenced in part by the reduced percentage of HCl as controlled by analysis of trial breakfasts, etc. In more elusive cases he would proceed further into stomach chemistry.

Deutsche medizinische Wochenschrift.

August 17, 1911.

Anaphylaxis in Human Pathology.—Menzer states that at the onset of an infectious disease the bacteria and their toxic products command the situation, the chief factors being the number and seat of the bacteria and the character of the toxins. The formation of an anaphylatoxin from the bacterial alubumin plays only a secondary rôle. In every severe infection the organism has to fight for its existence. It must check the penetration of bacteria and see to it that the toxic products of the latter as well as the catabolic substances formed in the issues are eliminated, including so-called anaphylatoxic products of bacteria. In tuberculosis the soluble products of the bacteria are especially active and engender an opsonic action at the foci of disease. Both the focal reaction and the subsequent general reaction from absorption are in evidence. In tuberculous anaphylaxis the disease foci are sensibilized and have an increased lability. In such cases tuberculin injections themselves may induce this oversensitiveness. Toxic material may be set free in amounts altogether disproportionate to the small quantity of tuberculin injected. The greater the degree of encapsulation of a focus the less the anaphylaxis. There is no true serum disease. What seems such is the aggravated reaction of a local focus with increased absorption of toxic products. Iodine has the power of mobilizing latent foci of disease.

Dangers of Effervescence in the Stomach in Diagnostic Procedures.—Nieden refers to the recently advocated diagnostic use of intragastric effervescence in connection with the Röntgen investigation of the stomach contents. This method goes back many years and might not need to be called to account had not the statement crept into textbooks that it is quite harmless. As far back as 1903 fatalities were upon record. Several patients with ulcer or cancer of the stomach lost their lives as a result of the use of Seidlitz powder or their equivalent for diagnostic purposes. As death did not supervene for a considerable interval the incrimination of the method might have been defective forensically. Morally, however, there is not much room for doubt that the fatal hemorrhages were due unconditionally to the act of effervescence. Whenever there is evidence that an ulcer of any sort is present in the mucosa such a test must be omitted. The question then comes up, may the sudden liberation of CO_2 cause fatal shock? This cannot be answered at present, but such shock might easily prove a contributory cause of death. The methods of insufflation may be too valuable to be given up unconditionally, but the author prefers the employment of "contrast forming substances" such as bismuth, barium, etc., for mapping out the stomach contours.

Pachymeningitis Hemorrhagica Interna in Infants.—Hahn states that quite recently we have obtained coherent information as to the existence of this affection in earliest infancy. He relates a case in detail and sums up what we know to date as follows: The condition represents a genuine pure fibrinous pachymeningitis with incidental hemorrhages. The latter were intradural and not upon an inflammatory basis, being associated with hydrocephalus externus. The localization was shown by the meningeal symptoms, the results of lumbar puncture and especially by the retinal hemorrhages. The entire syndrome appears to depend upon a friability of the blood-vessels, while the efficient cause is represented by traumatism. In the absence of a defective state of the blood-vessels the predisposing cause should lie in the blood itself. The hemorrhagic factor is evidently the source of much controversy; while essential to the syndrome it is not invariably in evidence macroscopically.

The Epileptic Syndrome in the Secondary Period of Syphilis.—Alfredo Rubino says that epilepsy occurring in syphilitics is of the Jacksonian type. It may occur in the secondary period of the disease, and should be considered as a neurosis of toxoinfective origin, with or without lesions of the cortico-motor area. Such lesions may be congestive, hemorrhagic, or inflammatory. There is not necessarily a congenital predisposition to nervous symptoms, but if this does exist there will be more liability to the occurrence of the epileptic symptoms. The epileptic symptoms disappear rapidly under the administration of anti-syphilitic remedies. When this is not the case the disease is either one of epileptic predisposition or of parasyphilitic origin. We should always think of the possibility of a secondary syphilitic epilepsy occurring after the age of 20 years, without previous nervous symptoms, even when syphilis is denied and there is no history or present symptom of the disease. Mercury should always be administered in these cases and its effects watched.—*Giornale Internazionale delle Scienze Mediche.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

OCCUPATION.

THE examiner should always notice carefully whether the occupation is correctly and definitely described in the application and report any dereliction. This precaution is a most important one, as it may be discovered that, in addition to the occupation as stated in the application, the applicant is engaged in some way in handling, selling, or manufacturing alcoholic beverages. The occupation may only appear in such cases as that of hotel keeper, merchant, or proprietor of a store, etc. Having cleared up this point beyond all doubt, the examiner may usually leave the matter for the further consideration of the home office, as every company has adopted its own classification of the relative influences of the various occupations on the duration of life in general. In some cases, however, it becomes his task to determine how far the applicant's particular employment may affect his individual longevity. One man may be so constituted that, though just at or possibly a little below the average physical condition, he is safely insurable provided all the circumstances connected with his occupation and his pecuniary means admit the probability that he will take the requisite care of himself. For instance, to the well-to-do merchant or professional man an occasional attack of catarrh or bronchitis may not necessarily excite apprehension, while the same ailments occurring in a person whose occupation constantly furnishes the exciting cause of such attacks, will suggest the possibility of more serious trouble eventually.

While the question of occupation, aside from the exceptions already mentioned, may usually be left to the decision of the home office, the examiner ought to have a general idea of the treatment of this subject by the different companies. Clergymen, lawyers, schoolmasters, and physicians make the best risks according to the order in which they are mentioned. Physicians are decidedly the poorest of the four on account of the demands upon their strength, irregular hours, and the liability to drug habits. Everything else being equal, outdoor labor is more healthy than indoor. Statistics make it clear that those engaged in agriculture head the scale in life value. Even seamen, though subjected to all kinds of exposure and vicissitudes of temperature, are remarkable for their high state of health. The evils of dusty trades are materially lessened when they are pursued in the open air or under sheds only partially closed. The occupation hazard may be classified into three groups:

1. The risk from increased liability to accident. Many of the iron and tin workers, coal miners, railway laborers, engineers, firemen, workers in electricity, fishermen, seamen, saw-mill operators, etc., are in this class.

2. The hazard on account of the diseases which may be occasioned. Stone cutters, copper and lead miners, grinders, file makers, lead, brass and copper workers, potters, glass makers, plumbers, painters, etc., are included in this group.

3. Occupations requiring the handling of alcoholics. In this class the majority of workers consume a large and constant quantity of alcohol and materially shorten their lives.

It is sometimes remarked that human life is the cheapest thing on earth. While this may still hold true to some extent, a great improvement in the conditions affecting workers has gradually come about through legislation, sanitary laws, political and educational privileges, and advance in wages. Mechanical devices have been adopted which materially reduce the risks incurred by employees, such as air brakes, automatic couplers, blowers for carrying off dust and gases, and various mechanical contrivances for doing parts of work formerly done by hand. Laws and sanitary measures will not, however, remedy all the evils arising from unhealthy occupations for reasons for which the working people themselves are responsible. Notwithstanding the efforts of some lawmakers to fasten all the liability and cost of damages upon employers, thereby ignoring the factor of contributory negligence, it requires no lengthened acquaintance with workmen to discern their recklessness, gross carelessness, frequent neglect of cleanliness, failure to make the most of preventive measures against evident dangers, and, above all, the too widespread habit of intemperance.

Some Auscultatory Problems in Insurance Examinations.—In a paper read at a meeting of the Life Assurance Medical Officers' Association R. A. Young discusses the problems of the insurance examiner which result from those departures from the generally accepted normal standards of auscultatory sounds that are yet compatible with health and those in which slight departures from the normal are the index of commencing disease or the stigma of past attacks, with a definite significance from an insurance standpoint.

Heart.—In cases of rapid pulse a differentiation must be made in its causation between nervousness due to the examination, hurrying after a meal, the toxic action of tobacco or alcohol, functional derangements such as cardiac neuroses and paroxysmal tachycardia, and serious disease such as valvular lesion with broken compensation, myocardial disease, exophthalmic goiter, and beginning tuberculosis. In the differentiation attention must be paid to the character of the heart sounds, the effect of posture, rest, and exercise. In any case of rapid heart action, not manifestly due to nervousness, postponement for reexamination is to be recommended. A slow pulse is of significance only if it is below 60 or if the applicant is no longer young. In all cases, however, the tension of the pulse, the size of the heart, and the character of the cardiac impulse should be noted. As to arrhythmia, a simple irregularity ranging with respiration in young subjects is of no serious importance, even though there may be occasional slight syncopal attacks. Irregularity due to tobacco, tea, or coffee, need not cause rejection if it ceases after abstinence or moderation. Extra-systoles in young and middle-aged applicants are not necessarily of serious import in the absence of arteriosclerosis or cardiac hypertrophy, but should always be regarded with suspicion. Irregularities due to heart-block, to weakened muscular power, or to valvular or other lesions should be regarded as sufficient cause for rejection.

The sounds of the heart may be weak or distant on account of thickness of the thoracic coverings—muscular, fatty, or emphysematous—or of serious myocardial degeneration—inflammatory, fatty, or fibroid. Accentuation of the second sounds at the base may indicate increased tension in the general or the pulmonary circulation, or may be due to uncovering of the heart by retraction of the lung. Loudness of the aortic second sound is of more importance than that of the pulmonary, since increased

tension of the pulmonary circulation may occur temporarily from any insignificant causes, such as simple holding of the breath. Absence of the second sound at the apex may occur in certain cases of mitral stenosis, and this in connection with sharpness of the first sound occurring in the same condition may give rise to an error in diagnosis unless the sounds are timed by the carotid pulse. Sharpness of the first sound may also occur in the nervous, rapid heart. A booming first sound is suggestive of hypertrophy. A high-pitched second sound should lead one to suspect high blood-pressure. A low-pitched and booming aortic second sound suggests the possibility of an aneurysm and should warn the examiner to look carefully for signs of intrathoracic pressure. A weak pulmonary second sound may be indicative of commencing failure of the right ventricle. Reduplication of the heart sounds may indicate organic disease or may be of no significance. A doubling of the first sound may point to ventricular failure in cases of high tension or of chronic interstitial nephritis. When reduplication of the second sound is habitual it is suggestive of pulmonary emphysema or valvular lesion of the heart. Murmurs may usually with care in examination be properly estimated, though it is sometimes difficult to determine the true significance of the murmur associated with mitral stenosis. It may not be audible in the erect position, a fact which accentuates the necessity of examining the heart in the recumbent as well as in the erect position. Functional and exocardial murmurs may cause error in diagnosis, but their origin should be recognized if care is exercised.

Respiratory System.—The problems arising during auscultation of the lungs are sometimes as puzzling as those encountered in the cardiac examination. It should be remembered that the physical signs in corresponding situations in the two lungs, especially at and near the apex, may differ considerably. The young examiner should early learn to appreciate the normal increase of vocal fremitus at the right apex. The breath sounds and the vocal resonance, as well as the percussion note, may be slightly higher pitched over the right supraspinous fossa. The examiner has therefore to form, almost subconsciously it may be, an idea of the normal standard for each side of the chest. In absolutely healthy persons wide variations in the breath sounds may exist over the upper part of the right lung; they may even be bronchovesicular in character, the voice sounds being also distinctly increased and vaguely bronchophonic—a combination which the textbooks give as an indication of early tuberculous deposit or of the scarring from a bygone arrested lesion. The difficulty of diagnosis is still further increased if the patient has a hairy chest or is sweating because of the spurious râles then produced. In such a case much aid may be obtained by inspection of the chest in a good light. Even in very early tuberculosis there may then be seen a slight lagging on the affected side, or the shoulder on the normal side may continue to rise during inspiration after that on the affected side has ceased. The breath sounds heard in some normal persons on the right side would, if heard at the left apex, almost certainly indicate tuberculosis. Weak breath sounds at the right apex with exaggeration at the left are to be regarded seriously. Weak breath sounds at one or other base indicate old pleurisy, fibrosis following on tuberculosis or pneumonia, or collapse; or they may be due to some abdominal disease interfering with the movements of the diaphragm. Cogwheel respiration may be due to forcible cardiac action or may occur in tuberculosis; when heard constantly at an apex it is very suggestive of early tuberculous deposit. Spurious râles, apart from those due to a hairy chest, are not uncommon, and are sometimes confusing. They may be caused by movements of the head or not infrequently by the deglutition of saliva. Fine collapse râles are often heard in normal chests on deep inspiration, and are difficult of explanation. Friction sounds heard over or near the heart, with a cardiac as well as a respiratory rhythm, indicate some pleural roughening; they may be unaccompanied by any other symptoms, but are suggestive of tuberculosis.

The Temptations of the Local Medical Examiner in Making Life Insurance Examinations.—J. E. Dildy of Lampasas, Tex., read a paper before the Section on Medicine and Diseases of Children of the State Medical Association of Texas, at Amarillo, on May 10, 1911, on the temptations of the local medical examiner in making life insurance examinations. Emerson's statement that legally the local examiner is the agent for the company, and not for the solicitor or the applicant, that he is employed to do a certain piece of work for so much money, is quoted with approval, and Dildy proceeds to point out some of the temptations to which a medical man is subject as an examiner for life insurance. The agent is generally a glib, smooth-spoken, affable individual, and the applicant is not infrequently an unhealthy person who has no right to be passed as sound. According to Dildy a doctor should be a good judge of character, and when he believes an applicant is padding his family or personal history he should insist on his telling the truth, the whole truth, and nothing but the truth. Should this insistence fail, the suspicion should be reported to the company; but medical men are tempted not to do it, for it makes more work and brings no more pay. Physicians are tempted to be careless in their methods of examination, are liable to overestimate the risk, and to hurry unduly. They are asked to assist the agent in obtaining new business, which is but a sly form of bribing. Dildy says there are other forms of temptation by which agents and applicants attempt to beguile the medical practitioner from the path of rectitude, but that those mentioned by him will suffice.—*Texas State Journal of Medicine*, July, 1911.

Official Tariff for Medical Attendance.—G. P. Forrester states that there is pending before the German Reichstag a bill requiring that every sick benefit society should draw up a regular agreement with medical practitioners who attend its members, according to which agreement the former are to be paid in accordance with the actual amount of ability and time required for treating any individual case. There is in existence in Germany an official scale of charges for professional services rendered by physicians and surgeons, whose provisions are legally applicable in case of dispute arising between patient and physician. Many sick clubs pay their medical men on the basis of this tariff, the physician agreeing to grant a rebate of from 10 to 20 per cent. of the total amount of his bill for attendance on members of the club. This agreement assures to the physician who engages in contract practice a more just and ample remuneration than generally prevails. The average sick-club doctor of Great Britain and Germany is paid a sum of seventy-five cents to one dollar and a half per annum for every member of the club. The American lodge doctor in many cases is not better off in this respect than his European colleagues. The Prussian scale of charges for professional men, as amended in 1906, contains a maximum and a minimum charge for each kind of service, the latter to be applicable in the case of the obviously poor. It enumerates in all 185 different medical functions.—*The Lancet*, May 13, 1911.

The Status of the Illegitimate Child in the Austrian System of State Insurance.—Korpert states that the Austrian insurance law which was enacted November 3, 1908, provides the same protection to the illegitimate child as to the legitimate if the deceased mother had been insured, or if the deceased father had fulfilled all of his legal obligations toward his child.—*Zietschrift für Säuglingsfürsorge*, Bd. III, 1911.

Book Reviews.

Diseases of the Nose, Throat, and Ear, Medical and Surgical. By William Lincoln Ballenger, M.D., Professor of Otology, Rhinology, and Laryngology, College of Physicians and Surgeons, Department of Medicine, University of Illinois, Chicago; Fellow of the American Laryngological Association; Fellow of the American Laryngological, Rhinological, and Otological Association; Fellow of the American Academy of Ophthalmology and Otolaryngology, etc. Third Edition, Revised and Enlarged. Illustrated with 506 engravings and 22 plates. Price $6.00. Philadelphia and New York: Lea & Febiger, 1911.

That three editions of this work should have appeared within three years is a significant record of its popularity. The author has succeeded in presenting a work that fully covers the entire subject of diseases of the nose, throat, and ear in a manner suitable not only for students and general practitioners, but also for specialists. Among the new features in this edition are sixty new drawings and five new plates, of which three are colored. Goldsmith's plastic operation for closure of recent perforations of the septum is described. Vaccine therapy is given prominence. The choice of a sinus operation is fully discussed. The Canfield-Ballenger operation is given as the simplest, most thorough, and most conservative procedure for the cure of chronic empyema of the antrum of Highmore. Fletcher's sphenoidal operation is described. Vincent's angina is given a place that was lacking in former editions. Sluder's operation for the removal of the tonsils with the capsule intact is given due prominence. The chapter dealing with foreign bodies in the larynx, trachea, bronchi, and esophagus has been thoroughly revised by Chevalier Jackson. Labyrinthine infections are presented from a broad clinical viewpoint. The comprehensive character of the contents of this book, together with the large number of illustrations, many of which show the successive steps of nearly every accepted operation, make the volume a combined textbook and atlas.

A Manual of Gynecology. By Thomas Watts Eden, M.D., C.M. (Edin.), F.R.C.P. (Lond.), F.R.C.S. (Edin.); Obstetric Physician, with Charge of Out-Patients, and Lecturer on Midwifery and Gynecology, Charing Cross Hospital; Surgeon to In-Patients, Chelsea Hospital for Women; Physician to In-Patients, Queen Charlotte's Lying-in Hospital; Examiner in Midwifery and Diseases of Women to the University of Oxford and to the Royal Army Medical College. With 272 illustrations in the text. Price $5.00. Philadelphia: P. Blakiston's Son & Co., 1911.

This book has been written with the object of providing for students and general practitioners an account of the diseases of women in their pathological and clinical aspects. Emphasis has been laid upon clinical and practical relationships rather than upon systematic pathology. The book is fairly complete, without being exhaustive. Part I deals with the anatomy and physiology of the female genital organs; Part II with methods of examination; Part III with certain prominent gynecological symptoms; Part IV with disorders of menstruation; Part V with morbid conditions of the uterus; Part VI with morbid conditions of the ovaries; Part VII with morbid conditions of the Fallopian tubes; Part VIII with pelvic inflammation; Part IX with extrauterine gestation; Part X with morbid conditions of the vagina and vulva; Part XI with malformations; Part XII with major gynecological operations; Part XIII with minor gynecological operations; Part XIV with after-treatment of major operations; and Part XV with therapeutic notes. The numerous illustrations are of a high order of excellence. The book may be recommended to students and practitioners as a clear and concise manual of gynecology in its practical aspects.

Foods and Their Adulteration. Origin, Manufacture, and Composition of Food Products; Infants' and Invalids' Foods; Detection of Common Adulterations and Food Standards. By Harvey W. Wiley, M.D., Ph.D. With 11 colored plates and 87 other illustrations. Second Edition, Revised and Enlarged. Price $4.00. Philadelphia: P. Blakiston's Son & Co., 1911.

The subject of foods is one that interests many different classes of readers: the physician and layman, the manufacturer and consumer, the farmer, dietician, sanitarian, institutional manager, legislator, chemist, and scientific teacher. The author has succeeded in writing a book that apparently supplies the needs of all these readers. The cordial reception that had been accorded to the first edition was at once a tribute to the popularity of the author and of the great demand that recent pure food agitation had created for an authoritative work upon this subject. Recent advances in addition to this demand have compelled the writing of a second edition in which many new features have been incorporated. The regulations for inspection and the rules and regulations for the enforcement of the Food and Drugs Act have been omitted, and the space saved has been devoted to an expansion of the article on infants' and invalids' foods and to a section dealing with simple tests for ordinary adulterations. The work is a veritable mine of information on the many phases of the subject of foods: their relative physiological value, their origin, preparation, preservation, industrial aspects, and the effects of their deterioration. The section dealing with milk and its products presents this subject in a thorough manner. Physicians in general and pediatrists in particular will find the section on infants' and invalids' foods a complete digest of modern knowledge upon this subject. The detailed dietaries for special diseased conditions will be found particularly helpful. The fads in dietetics, forced feeding, economy in nutrition, meat-free diet, etc., are all given proper attention. The chapter on the simple methods of detecting food adulterations is a valuable addition to this work, which may be recommended both as a textbook and a book of reference.

A Brief Text of Physiology; for Dental, Pre-Medical, and College Students. By Carl J. Wiggers, M.D., Department of Physiology, University of Michigan. Forty-seven illustrations. Ann Arbor: George Wahr.

This is an elementary book designed for the use of dental students. At the end of each chapter is a useful tabular summary. The explanatory text which accompanies many of the illustrations is so small as to be illegible, and this feature alone should prevent the use of the book in any college or school. Some of the statements are inaccurate, probably from an effort after condensation and brevity.

A Pocket-Book of Treatment. By Ralph Winnington Leftwich, M.D., late Assistant Physician to the East London Children's Hospital, Author of "An Index of Symptoms," "Syphonage in the Large Intestine," etc. Price $1.70. New York: Longman's, Green & Co.; London: Edward Arnold, 1911.

This is a flexible pocket manual bound in leather, and is somewhat like the numerous pocket formularies that have been issued in this country. The first part of the book deals with the armory of healing: symptomatic, nature, and drug treatment; incompatibles, flavorings, new remedies, dietetics, including food values and special dietaries, infant feeding, invalid drinks and dishes, baths and a list of spas, massage, exercises, serum therapy, Bier's hyperemic treatment, operative treatment, and a list of poisons and their antidotes. Part II takes up the diseases in alphabetical order, and gives in each case brief directions as to management, and a list of suitable prescriptions. One notes in the fluid mixtures the English custom of using the fluid ounce as the basis of the dose. This is somewhat confusing to American readers, who are accustomed to the dram as the unit of dosage. Another disadvantage is the unfamiliarity of Americans with the preparations of the British pharmacopœia, many of which appear in the prescriptions. Nevertheless, the methods of treatment are in accordance with the most advanced and up-to-date practice, and their presentation is valuable for their conciseness and for the emphasis laid upon the most essential features. The book bears the impress of the experienced clinician, who appreciates the needs of the general practitioner, and the impress of the accomplished author of condensed manuals.

Enlargement of the Prostate; Its Treatment and Radical Cure. By C. Mansell Moullin, M.D. (Oxon.), F.R.C.S., Vice-President of the Royal College of Surgeons, Consulting Surgeon to the London Hospital, late Examiner in Surgery at the Universities of Oxford and Cambridge, Lecturer on Surgery at the London Hospital, Radcliffe's Traveling Fellow and Fellow of Pembroke College, Oxford, and Hunterian Professor at the Royal College of Surgeons. Fourth Edition. Price $1.75 net. P. Blakiston's Son & Co., Philadelphia, 1911.

On reading this work one readily understands why it appears in a fourth edition. Within its 172 pages the author encompasses his subject in a concise and masterly manner. The description of the mechanical factors involved in prostatic enlargement, their causes and effects, merits especial praise. In the section on treatment he has omitted all details and modifications of operations which have only historic interest, confining himself to those methods of treatment of proven value. Technique of diagnostic and therapeutic procedures is but briefly sketched, full credit being accorded contemporary workers in this field. In all regards the work is excellent.

Landmarks and Surface Markings of the Human Body. By L. Bathe Rawling, M.B., B.C. (Cantab.), F.R.C.S. (Eng.), Surgeon with Charge of Out-Patients, Demonstrator of Practical and Operative Surgery, late Senior Demonstrator of Anatomy at St. Bartholomew's Hospital; late Assistant Surgeon to the German Hospital, Dalston; late Hunterian Professor Royal College of Surgeons, England, etc. With 31 illustrations. Fourth Edition. Price $2.00. New York: Paul B. Hoeber, 1911.

In this work the author presents in a clear and concise manner the more important landmarks of the human body. The book is small, consisting of less than a hundred pages. What is given is well selected, but prospective purchasers will probably think that they can obtain something just as good for less money.

The Johns Hopkins Hospital Reports. Vol. XVI. Price $5.00. Baltimore: The Johns Hopkins Press, 1911.

This is a substantial volume of 670 pages, comprising the results of five important investigations, each of which forms a complete monograph. These studies are as follows: (1) Studies in the experimental production of tuberculosis in the genitourinary organs, by George Walker, M.D. (2) The effect on breeding of the removal of the prostate gland or of the vesiculæ seminales, or of both; together with observations on the condition of the testes after such operations on white rats, by George Walker, M.D. (3) Scalping accidents, by John Staige Davis, M.D. (4) Obstruction of the inferior vena cava, with a report of eighteen cases, by J. Hall Pleasants, M.D. (5) Physiological and pharmacological studies on cardiac tonicity in mammals, by Percival Douglas Cameron, M.D. The first of these studies is described in 222 pages of the text. The object of this study was to determine experimentally the different modes by which the genitourinary organs of the male can be infected, and to observe the spread of the disease from one organ to another along the tract. A limited study of the disease in the female was also made. The author notes the following points of surgical significance: Tuberculous processes in the genitourinary organs have two initial points—the glomeruli of the kidneys and the tubules of the epididymes. For practical surgical consideration these are the only sites which need to be taken into consideration. Primary tuberculosis of the bladder never occurs, and primary tuberculosis of the prostate or vesicles is so rare that it may be discarded. The literature of the subject is exhaustively covered and an extended bibliography is appended. The monograph on scalping accidents is a most scholarly contribution to surgical treatment. It comprises a detailed report of two unpublished cases, historical data, anatomical considerations, definition, etiology, mechanism, case reports with summaries of each, symptoms, complicatory prognosis, treatment, animal experiments, and comments. The author justly states that in textbooks and systems of surgery scalping is generally considered under "lacerated wounds of the scalp," but is undoubtedly a lesion whose treatment requires more careful study and attention than is usually accorded it. The paper is based on a critical review of the literature, the author's experimental work, and on two cases of complete scalping. The monograph on "obstruction of the vena cava with a report of eighteen cases" is a substantial contribution of 186 pages, comprising a complete study of this subject. The paper on cardiac tonicity is concerned with the accurate study of the variations which take place in mammals and in man under psysiological and pathological conditions and under the influence of drugs. This brief summary of the contents of this volume can give no adequate conception of the wealth of data filling its pages. It forms a valuable addition to a well-known and highly appreciated series of volumes.

Feeblemindedness in Children of School Age. By C. Paget Lapage, M.D., M.R.C.P., Lecturer in School Hygiene to the Manchester University, and Physician to the Manchester Children's Hospital. With an Appendix on Treatment and Training, by Mary Dendy, M.A., Price $1.60. New York: Longmans, Green & Co., 1911.

The fact that one out of every hundred children of school age is feebleminded makes the subject of the care of feebleminded children one that public and educational authorities cannot ignore. There is a general recognition of the importance of effective methods in dealing with this class of children. School medical officers, teachers, and social workers will find in this volume valuable information upon this subject. The book further emphasizes the importance to the public of efficient care of feebleminded persons: the rôle of heredity in the causation of feeblemindedness, and the importance of suitable supervision and care which will last during the whole lifetime of the feebleminded person. The book presents detailed statistical information and discusses physical and mental characteristics, defects of speech, special types, diagnosis, prognosis, care, and treatment. The biological aspects of inheritance, the inherited and acquired factors, and the value of preventive measures are fully discussed. The author does not endorse the plan of asexualization, stating that "lifelong supervision, which, though more costly, is so necessary for other reasons, should, if efficient, be an equally good safeguard against the propagation of the taint to future generations." The chapter on the training and treatment of feebleminded children is sufficiently detailed to be of service as a daily guide to those who are put in charge of mentally defective children. There are also directions for the detailed examination of the head and of speech, a suitable school farm and certificate, and a list of homes, schools and institutions in England. The volume may be recommended as a valuable textbook upon this subject.

The Chemistry of Synthetic Drugs. By Percy May, B.Sc. (Lond.). Price $2.25. London, New York, Bombay, and Calcutta; Longmans, Green & Co., 1911.

In this book will be found some account of the main facts concerning synthetic drugs and the principles involved in their production. Further, whenever possible, the reactions which take place between a drug and the organism are dwelt upon. Brief mention is also made of the therapeutic effect of some of the drugs. The chief value of the work lies in its possibility of interesting physicians in the applications of chemistry to therapeutics and pharmacology, and in providing literature more reliable and scientific than that which accompanies each new synthetic from the place where it is manufactured or sold.

Modern Surgical Technique in Its Relation to Operations and Wound Treatment. By C. Yelverton Pearson, M.D., M.Ch., F.R.C.S., Professor of Surgery, University College, Cork; Senator of the National University of Ireland; Fellow and Examiner in Surgery, late Royal University of Ireland; Surgeon to the North Charitable Infirmary and County and City of Cork General Hospital; Surgeon to the County and City of Cork Victoria Hospital for Women and Children; Hon. Obstetrical Surgeon to the County and City of Cork Lying-in Hospital; Hon. Life Member of the Austin Flint Med. Assoc., Iowa, U. S. A. Illustrated with two colored and other plates and 129 illustrations in text. Second Edition, Revised and Enlarged. Price $4.00. New York: William Wood & Company, 1911.

This work is thoroughly representative of the surgical technique of the present day, and, while it can by no means take the place of the standard textbooks, it will form a most useful supplement to any of them. The subjects discussed in this volume are: Surgical Bacteriology; Infection; Disinfection; Standardization of Disinfectants; Germicides and Antiseptics; Antiseptic Solutions, Emulsions, and Pastes; Disinfection of the Hands; the Use of Gloves and Operating Costume; Preparation of the Patient's Skin and Mucous Membranes; Preparation and Sterilization of Instruments, Sponges, Ligature and Suture Materials; Nature of Absorbent Dressings and Their Mode of Sterilization; Antiseptic Dressings; Sterilization of Water; Wounds: Their Nature and Treatment; Prevention and Arrest of Hemorrhage; the Operation; Treatment after Operation; Renewal of Dressings; Operations in Private Houses; and Asepsis in General Practice. To all who do any surgical work, whether much or little, this volume will prove serviceable. It is well printed and well illustrated, and has a good index.

One Thousand Surgical Suggestions. Practical Brevities in Diagnosis and Treatment. By Walter M. Brickner, B.S., M.D. (New York), Adjunct Surgeon Mount Sinai Hospital, Editor-in-Chief *American Journal of Surgery*. With the collaboration of Eli Moschcowitz, M.D., James P. Warbasse, M.D., Harold Hasy, M.D., and Harold Neuhof, M.D., New York, Associate Editors *American Journal of Surgery*. Fourth American Edition. Price $2.25. New York: Surgery Publishing Co., 1911.

Four editions of this work have appeared since 1906, and the number of suggestions has grown from 500 in the second edition to 1,000 in the present edition. The "suggestions" cover the entire domain of surgery, and are classified, according to the various regions of the body and according to various procedures and conditions, as fractures, infusion and transfusion, instruments, sutures, etc. The book, which is well printed and bound, cannot fail to supply many helpful "tips" to the general practitioner and surgeon.

Criminal Man. According to the Classification of Cesare Lombroso. Briefly summarized by his daughter, Gina Lombroso Ferrero. With an introduction by Cesare Lombroro. Illustrated. New York and London: G. P. Putnam's Sons, 1911.

It is a strange circumstance that America, which has been the first country to respond to the ideas of the modern school of criminology founded by Lombroso, as evidenced by the Elmira Reformatory, the Probation System, Juvenile Courts, and the George Junior Republic, does not possess a complete translation of Lombroso's works. In fact, the only works in the English language are the volume on the female offender, the article on criminal anthropology in the "Twentieth Century Practice of Medicine," and the volume on the man of genius. The daughter of the late Italian psychiatrist and criminologist has supplied a distinct want by presenting in a single volume a summary of the conclusions reached by Lombroso on the causes of criminality and the treatment of criminals. The introduction to this volume was written by Professor Lombroso just before his death. The book is divided into three parts. Part I, entitled "The Criminal World," comprises chapters on the born criminal and his relation to moral insanity and epilepsy, the insane criminal, and criminaloids. Part II takes up the subject of the origin and causes of crime, the prevention of crime, and methods for the cure and repression of crime. Part III includes chapters on the examination of criminals and on the discrimination between criminals and lunatics, and in detecting simulations of insanity. The Appendix presents a brief summary of the works of Lombroso, as follows: the man of genius, criminal man, the female offender, political crime, too soon (a criticism of the new Italian penal code; prison palimpsests, studies in prison inscriptions); ancient and modern crimes; diagnostic methods of legal psychiatry; anarchists; lectures on legal medicine; and recent discoveries in psychiatry and criminal anthropology, and the practical application of these sciences. There is also appended a bibliography of the chief works of Lombroso. The theories of the latter, although at first warmly criticised, have not only gained recognition as established facts, but have become the starting point of definite reforms in prison management, in the reformation of criminals in legislation and in legal procedure. The pen of the gifted daughter describes in elegant diction the pith of Lombroso's epoch-making teachings. The latter was the first to perceive in the criminal an example of atavism, which explained the "enormous jaws, high cheekbones, prominent superciliany arches, solitary lines in the palms, extreme size of the orbits, handle-shaped or sessile ears, insensibility to pain, extremely acute sight, tattooing, excessive idleness, love of orgies, and the irresistible craving for evil for its own sake, the desire not only to extinguish life in the victim, but to mutilate the corpse, tear its flesh and drink its blood." The born criminal contributes 33 per cent. to the sum total of criminality. One-half of the criminals are classed as criminaloids, who possess the "virus", so to speak, in an attenuated form. These criminaloids represent the "ultra-violet ray of the criminal spectrum, of which the vulgar criminal represents the ultra-red." These offenders stand in a class by themselves. One very interesting subject in relation to criminal anthropology is that of symbiosis, "the utilization of antisocial elements, thus redeeming them completely and justifying their existence in the eyes of mankind and in the scheme of Nature." As examples of this practice are mentioned the galleries and fortifications cut out in the rocks at Gibraltar and Malta by English convicts and the complete transformation of parts of Sardinia. It is stated that "the colonization of wild regions and all professions (motoring, cycling, acrobatic and circus feats) which demand audacity, activity, love of adventure and intense efforts followed by long periods of relapse and eminently suited to criminals." As regards the exploits of certain modern motorists one may agree that occasional criminal tendencies have found a natural outlet. It will certainly not appeal to the pride and dignity of the militant to be told that "war, the original, perpetual and exclusive occupation of our ancestors, is eminently suited to the tendencies of criminals" that "all the characteristics of the criminal, impulsiveness, cynicism, physical and moral insensibility, and invulurability are valuable qualities in the soldier in times of war, especially when waged against savage and barbarous nations, when cunning and ability have to be employed agaist primitive races who laugh at the rules and ethics of civilized warfare." To the general reader, as well as to the sociologist, jurist, lawyer, educator, and physician, this book cannot fail to provide an entertaining and at the same time most instructive insight into the philosophy of crime.

Diseases of the Stomach and Intestines. By Boardman Reed, M.D., Member of the American Medical Association, American Climatological Association, American Academy of Medicine, Foreign Member of the French Societé d'Electrothérapie; Consulting Gastroenterologist to the Pottenger Sanatorium, Monrovia, Cal.; Consulting Physician to the Corey Sanatorium and Hospital, Alhambra, Cal.; Late Professor of Diseases of the Gastrointestinal Tract, Hygiene, and Climatology in the Department of Medicine of Temple University; Late Physician-in-chief to the Samaritan Hospital; Late Physician to the American Oneologic Hospital, Philadelphia, etc. Illustrated. Third Edition, thoroughly revised and largely rewritten. Price $5. New York: E. B. Treat & Co., 1911.

In this volume of about 1,000 pages nothing of importance in the modern developments of gastroenterology has escaped the author. In the preparation of this, the third edition, the entire text has been revised and largely rewritten, including 230 pages of new or substituted matter. A new chapter has been added on arteriosclerosis in relation to the affections of the gastrointestinal tract. The plan of this work and the thorough manner in which all phases of the subject are treated commend it to the general practitioner. Part I deals with anatomical, physiological, chemical, and diagnostic data. Part II describes methods of examination, and includes an excellent symptomatic guide to diagnosis. Part III discusses the methods of treatment. Part IV is entitled the gastrointestinal clinic, and takes up separately the various functional and organic diseases of the gastrointestinal tract. As an example of the thorough manner in which the entire subject is presented one may cite the chapters comprising the section dealing with the methods of treatment. There is a separate chapter, or, as termed by the author, lecture, on each one of the following subjects: prophylaxis and food requirements; general considerations concerning diet and dietotherapy; the diet in irritative and atonic conditions; sugar, spices, etc., in gastrointestinal cases; the author's and other series of diets; feeding by other routes than the mouth; methods of treatment; exercises; massage and rest; electricity, including high frequency and polyphase currents; electric and hydroelectric currents applied directly within the bowel; mechanical methods of treatment, as vibration; intragastric methods, as lavage and sprays; medicinal treatment; digestants, alkalies, and natural spring waters; tonics, stimulants, and sedatives; antiseptics, astringents, and laxatives.

Technique de Stérilisation. Par Ern. Gérard, Professeur de Pharmacologie à la Faculté de Médecine et de Pharmacie de Lille. Deuxième édition augmentée. Price 6 fr. Paris: Vigot Frères, Éditeurs, 1911.

This book is primarily intended for the manufacturing pharmacist, but contains many facts of interest and value to the general practitioner. Since the appearance of the first edition four years ago the developments in the domain of asepsis have been so great as to demand the addition of new material and the extensive revision of much of the old. The chapter on the sterilization of drinking water by the ultra-violet ray and that on the disinfection of infected rooms or conveyances are entirely new. The chapter on the preparation of sterile ampoules is particularly complete and the directions for the disinfection of books are admirable. A large space is devoted to the sterilization and care of ligature material. The book is attractively published and is of convenient size.

Food and the Principles of Dietetics. By Robert Hutchison, M.D. (Edin.), F.R.C.P., Physician to the London Hospital, Physician with Charge of Out-Patients to the Hospital for Sick Children, Great Ormond Street; author of "Lectures on Diseases of Children," "Patent Foods and Patent Medicines," "Applied Physiology"; joint author of "Clinical Methods." With plates and diagrams. Third Edition. Price $3.00. New York: William Wood & Company, 1911.

The third edition of Hutchison's valuable book has undergone a thorough revision, and the chapters dealing with "Principles of Feeding in Disease" have been considerably enlarged. There is also a new chapter on "Some Dietetic Cures and Systems." The book is well adapted for students and practitioners of medicine, and it will also prove serviceable to anyone desirous of acquiring some knowledge of foods and the problems of nutrition. A feature of the work is the space devoted to patent and proprietary foods, and we notice with pleasure the very fair treatment that these foods receive at the hands of the author. There are few books on this subject which are of much use to the medical practitioner, and fewer still which have reached a third edition.

Society Reports.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Meeting Held April 17, 1911.

The President, Dr. Reynold Webb Wilcox, in the Chair.

An Operation for the Relief of Tuberculous Peritonitis.—Dr. Aspinwall Judd said that several years ago it was his privilege to observe the results obtained in a number of cases of this affection by Dr. Samuel Lloyd with a technique which, in a modified form, he himself had adopted. In Dr. Judd's operation the incision, three or four inches in length, was made through the sheath of the right rectus muscle and, the diagnosis of tuberculous peritonitis having been established, the patient was eviscerated as far as possible. The intestines, caught in a nest of hot moist towels, were thoroughly washed with a 50 per cent solution of hydrogen peroxide, and the abdominal cavity completely flushed with the same, after which the cavity and intestines were thoroughly flushed and washed with normal saline solution. The incision wound was closed with three layers of sutures, and primary union had followed in every case in which he had operated. He said he would like to emphasize the following points: 1, The use of oxygen peroxide, 50 per cent for diagnosis and to destroy the tubercles. 2, The thorough flushing of the abdominal cavity, so that the peroxide might come in contact with all infected areas. 3. The necessity of primary union and the promotion of this by the peroxide. 4, The necessity of getting these patients out of bed at as early a date as possible. They did badly if housed or kept on their backs. 5. The necessity of after-treatment in the form of hygienic environment, hypernutrition, and appropriate drugs. During the past four or five years he had operated upon some 22 patients, 19 adults and 3 children. In almost all cases the primary improvement was very marked, though in some this was only temporary. In four a second operation was required, but the latter was followed by a completely successful result. In four, these being in an advanced stage of the disease, with considerable involvement of the lungs or other organs, there was no permanent improvement. Five were cases of primary tubercular appendicitis, and were operated upon as chronic appendicitis. No general flushing or evisceration was attempted, but the patients were completely relieved of their symptoms by the operation. Dr. Judd said the improvement in his cases had been truly remarkable, most of the patients gaining from twenty to sixty pounds within six months after being operated on. While, of course, it was too early to claim a cure, and while he would not be surprised to meet with relapses, still the results already accomplished, coupled with the cases of Dr. Lloyd, led him to believe that in this method there had been achieved a considerable advance in the treatment of tuberculous peritonitis.

A Review of Methods of Examination in Heart and Blood-Vessel Disease, with Special Reference to the Discovery of Therapeutic Indications.—Dr. Louis F. Bishop said that while until quite recently the examination of the cardiovascular system consisted chiefly in feeling the pulse and in the auscultation of the heart, there had now been added to these methods the measurement of blood-pressure, the more accurate observation of the wave motions in the blood current, the consideration of the properties of the blood, the *X*-ray examination of the heart, and the electrical study of the cardiac contractions, as well as the study of the chemistry of the body as influencing structural and functional disorder of the cardiovascular system. The most elementary point as regarded the therapeutic indications of blood-pressure findings was that low pressure was not necessarily to be raised or high pressure necessarily lowered. Still, high blood-pressure had a profound therapeutic indication, the limitation of the protein content of the food to the actual requirements of the body; and it also called for the ordering of outdoor exercise and the restriction of mental work and worry. Low blood-pressure, as an acute condition, demanded, according to the nature of the case, a vigorous attack upon some existing form of toxemia, the conservation of nervous energy, as in conditions of shock, attention to posture, and the use of stimulants such as external heat, saline infusion, ammonia and alcohol. In chronic cases the observation of blood-pressure led one to be more or less vigorous in our supervision. One established in each instance a certain standard for a possible approach to normal in blood-pressure, and tried to adhere to it. In many cases of severe cardiac disease there existed a condition of the auricle giving rise to a very large number of impulses (fibrillation), and, these being transmitted to the ventricle, whose capacity to respond was not equal to the many contractions, there resulted great irregularity. In such, digitalis, by retarding the transmission of impulses through the bundle and stopping some of them entirely at this point, brought about a slowing of the radial pulse and a functional improvement of the heart's action. Poylgraph tracings enabled one to detect both extra auricular systoles and extra ventricular systoles. These of themselves had no therapeutic indication, but they might be mistaken for other forms of irregularity. The electrocardiogram, as to its therapeutic indications, was much the same as the polygraph, but with some additional things, such as the detection of right-sided hypertrophy by the inverted electrocardiogram. The therapeutic indications discovered by laboratory examinations of the urine, blood and feces in his opinion, were on an equal basis of importance with examinations of the heart and blood-vessels themselves. One thus found the evidence of intestinal putrefaction, which he believed to be the most usual cause of arteriosclerosis. The discovery of intestinal putrefaction indicated the avoidance of alkaline laxatives. The other therapeutic indications were the use of castor oil at regular intervals, the use of the less fermentable carbohydrates, the insistence on outdoor exercise, and, possibly, irrigation of the large intestine; together with the low protein diet. In the blood one discovered the compensatory increase of red blood cells in valvular disease in young people. In many cases of arteriosclerosis also there was a large increase of these cells, though here accompanied with anemia, in the sense of low hemoglobin, indicating plain diet and outdoor life, with the avoidance of all tonic drug treatment. Treatment was to be chiefly directed toward influencing the digestive tract and the composition of the blood. The condition of the heart and blood-vessels would determine the great question of rest and exercise, careful tests of the effect being made. The *X*-ray had been of great value in the more certain diagnosis of the condition of the heart. It was of particular service, in the speaker's opinion, in showing distinctions between essentially valvular cases and those secondary to arteriosclerosis. He next proceeded to speak of inspection, palpation, percussion, and auscultation, and under the last named treated at some length of the heart sounds and the various murmurs. He then took up the study of the pulse, stating that of late years the tendency had been to place less reliance upon the judgment founded solely on the pulse, as felt, and to modify the findings by the actual measurements of the sphymomanometer and the study of tracings. Not very long ago it was customary to treat the high tension pulse systematically with nitroglycerin. One was not to reduce the strength of such a pulse arbitrarily, but always by removing the cause. In the case of a weak pulse with a low pressure reading the general indication was, of course,

to strengthen it, but this was not to be done directly by stimulation, provided there were no side symptoms of defective circulation. In all cases of cardiac or vascular disease the history of the patient, as well as his personality, and the measure of his resources, would naturally influence very considerably the advice given him. In concluding, Dr. Bishop said it was worth something to know that the treatment of cardiovascular disease must be founded upon proper training and experience in the interpretation of one's technical findings as a whole, and in his opinion it was not worth while to seek for very many specific indications in the findings of technical methods.

High Blood Pressure and Its Causes.—Dr. Oliver T. Osborne, Professor of Materia Medica and Therapeutics in Yale University, opened the discussion with some remarks on high blood-pressure. Syphilis and the various infectious febrile diseases, he said, were only incidental causes of this. Why was it that cardiovascular and renal disease were so much on the increase at the present day? Year by year apoplexy was getting younger men, weak hearts were more in evidence, and Bright's disease was increasing. This state of affairs was largely due to the general stress of modern life, including a great variety of sensory irritations, such as light, noise, shock, and fear. Whether one drove automobiles oneself or walked the busy streets one was subjected to a constant strain. Fear was a potent factor, especially in the case of children. So, there was a continually increasing vascular tension. Old and young alike were engaged in both physical and mental competition. Day after day one rushed from one appointment to another. One ate too much meat and drank too much water. While less alcohol was indulged in than formerly, more tea and coffee were consumed. Consequently, more caffeine was taken into the system, and this was a cerebral irritant. The blood-pressure might be lowered by means of rest and a milk diet. Alcohol also had this effect, by flushing the peripheral circulation. Exhaustion and neurasthenia resulted from lowering of the blood-pressure. Normal blood-pressure was principally the result of the action of the suprarenals and, to a less extent, of the pituitary body, while the thyroid and most of the secretory glands had the effect of lowering the pressure. Consequently, anything that would exhaust or tire out the thyroid would tend to raise the blood-pressure. With abnormally high pressure one would have such symptoms as increased urination, flushings, etc., indicating the beginning of cardiorenal disease. When the blood-pressure was too high, what should one do? Not too much. The pathological process could be arrested if taken in time. The patient should be ordered to take rest, the quantity of meat eaten should be reduced, and intestinal putrefaction should be looked after. Frequently a small amount of thyroid, not more than two or three grains a day, would be of service. Or, one might give a little nitroglycerin. According to laboratory results, the action of this agent was extremely evanescent, but clinically this was not found to be the case: 1/200, or even 1/400 grain might be sufficient. One should give just enough to relieve the symptoms. The reason why iodine had been so long in repute in these conditions was simply because it had the effect of stimulating the thyroid, so that it would reduce the blood-pressure to normal. Body-baking was an efficient resource in lowered compensation and arteriosclerosis. It should, however, be employed in moderation: once a week at first, and then every two or three weeks. As to raising the blood-pressure, this could not be done if neurasthenia were present. As an actual remedy digitalis was to be relied upon, and strophanthus was useful in acute trouble. All other cardiac drugs Dr. Osborne would do away with. Strychnine was apt to harm. He believed that it was a mistake to use it, and that it had been too much resorted to. Alcohol might be of service, by dilating the peripheral vessels. Of late the blood-pressure proposition had become a fearsome sort of thing, and this was largely due to life insurance examiners. The ideas concerning it constituted a very bad nervous element. Consequently, Dr. Osborne did all that he could to discourage his patients from thinking about the subject, and he never took the blood-pressure unless he needed it for therapeutic reasons. In concluding he said he would liken our present-day life to the second speed of an automobile. With this, more gasoline and more lubricating oil were used, and more work was required to keep the engine cool. There was also more smoke, and when the car stopped it took quite a long time for the machinery to cool off. This was bad for the engine and bad for the rest of the apparatus, and it was hard work to adjust the fuel and weight.

Clinical Polygraphy: A New Instrument.—Dr. Thomas Satterthwaite described briefly the mechanism of the modern polygraphic machines, and the methods of using them so as to secure records of the jugular, liver, carotid and radial pulses, the apex beats of both right and left ventricles, and the respiratory movements. Allusion was made to the polygraphic instruments of Marey, Gibson, Mackenzie, Barringer, Berkeley, and others. The speaker believed the machine of Barringer to be the best of the kind for hospital work, while the Berkeley, being simple, inexpensive, and portable, was especially suited for ordinary practice. He then described his own machine, which he had been using for more than seven years in his office practice. It was called the Automatic Spring Recorder, because it eliminated the personal equation, as did the electrographic machines, and made use of the spring of the ordinary bath-room scales. The instrument was described as follows: "The pen-arm is actuated by the spring of the ordinary bath-room scales, to the platform or base of which a raised seat is firmly attached. The patient stands or sits upon the scales; or, by elevating the wings of the seat, it is made into a couch on which he may extend himself horizontally. The action of the heart and vessels is communicated to the pen-arm attached to the dial, which records the waves on the smoked paper of the revolving drum. Below it another pen-arm, made of rye-straw and tipped with platinum or celluloid, receives the impulse of the carotid or jugular or liver pulse, or of the apex beat, through a brass reservoir, and writes the curves on the same paper. Still below this, the metal pen-arm of a Jaquet chronograph marks the time on the drum in seconds or fractions of seconds." Illustrations of the recorder and polygrams taken by it were shown. While this instrument was capable of doing any of the work of the ordinary machine by the use of the time-marker and the receivers, tubes, tambours and pen-arms of the Mackenzie system, the speaker had used it with special advantage in determining the effects of nicotine, glonoin, and, recently, caffeine on the heart. As presenting a graphic record of the action of these drugs, it was a new aid in pharmacodynamics. With respect to the effects produced by the alkaloid caffeine, he showed a series of polygrams illustrative of experiments in which he had given massive doses of caffeine to a healthy adult man, the amount given being 42 grains within 50 minutes, whereas the pharmaceutical dose was 1 grain. The polygrams as interpreted showed the rate of the pulse and respiration before, during and after the experiments; also the rhythm and the cardiac force, together with all the waves and wavelets designated by Einthoven in his schematic representation of a cardiac cycle.

Sphygmographic Methods.—Dr. Richard Van Santvoord read this paper. (See page 512.)

Stethoscopic Examinations.—Dr. Robert Abrahams said that the stethoscope had stood the test of time, and

still remained the handmaid of every practising physician. Most of the stethoscopes intended for the examination of the heart were defective in that the chest-piece was made too large. Thus it necessarily rested on the adjoining ribs and, air entering underneath it, the proper conduction of the sound or murmur was interfered with. For a long time he had used the stethoscope for the diagnosis of pericardial effusion. The instrument was placed one or two inches beyond the normal boundaries of the heart, laterally, and the patient made to repeat "1, 2, 3." The words would be heard distinctly as long as it rested on lung tissue, but the instant it reached the effusion the sound would be cut off. It was not necessary that the effusion should be very large in order to produce this effect, especially when the patient was in a reclining position. He could confidently state that by the use of this method one could, with very little effort, map out the normal heart and ascertain the dimensions of a hypertrophied and dilated heart, as well as determine the relative size of the superficial and deep areas of the heart, both in health and disease. The principle on which all this was based was simply that, while the spoken or whispered word sounded clear and distinct over lung, it became less clear when the stethoscope reached the border of the heart. The average physician perceived and appreciated respiratory sounds much better than percussion notes, and there was such a great difference in the faculty of perceiving the latter, even among those who had been long in practice, that he believed this method of stethoscopic auscultation would commend itself generally. It should not be confounded with the old and very unsatisfactory method of auscultatory percussion, which was now rarely resorted to. The greatest usefulness of the stethoscope was, naturally, in the interpretation of the sounds and murmurs of the heart. While everyone recognized that the first sound was louder and stronger at the apex, and the second sound at the aortic area, there was a general disregard of the fact that, except in childhood, the aortic second sound was louder than the pulmonic second. The practical point here was that if the pulmonic second was more strongly accentuated than the aortic second, almost invariably, other things being equal, mitral disease was present. This point was of special value in the diagnosis of mitral stenosis, where the murmur was frequently absent or inconstant, while the presystolic thrill might never have been present. There were two features in this valvular disease which the stethoscope would never fail to emphasize, the pulmonic second sound and the thud-like thump of the first sound at the apex. Moreover, this prominence of the pulmonary second was of material assistance in the prognosis and treatment. If the sound lost its accustomed accentuation it was a sign of failure of the right heart, while if, under treatment, it again became loud and strong, it was an indication of restored compensation. He had used the qualifying phrase "other things being equal" because the second pulmonic sound exceeded the aortic second in the following other diseases: chronic bronchitis, substantive emphysema, and incipient pulmonary tuberculosis involving the apices especially. These affections, therefore, would have to be excluded before ascribing the accentuated pulmonic to mitral disease. A murmur heard over the pulmonic area should not invariably be designated hemic, anemic or functional, as it might possibly be the continuation of an aortic systolic murmur due to aortic stenosis or, again, result from stenosis of the pulmonary valves of congenital origin. The quality of a hemic murmur, however, was soft, and its point of maximum intensity was slightly above its place of origin, while in the great majority of instances it was transmitted upward toward the left clavicle. If the pulmonic systolic murmur were a continuation of an aortic one it would be found that as the stethoscope was moved from the pulmonic to the aortic area the murmur would increase in intensity, and if the murmur were abnormally loud and harsh, with a point of intensity directly over the pulmonic area and with little or no transmissibility, it should be considered as due to pulmonary stenosis. Mild pulmonary stenosis was of more frequent occurrence than was generally supposed. A good rule to go by was that when a loud, harsh murmur, heard at the left second intercostal space, close to the sternum, did not disappear under a reasonably long ferruginous treatment it was to be regarded as due to pulmonary stenosis. There was a type of mitral affection, more often seen in children than in adults, which was generally the result of rheumatic trouble and which sooner or later was accompanied by chorea. In these cases there was a mitral systolic murmur, and although not attended by displacement of the apex it was to be considered an expression of mitral insufficiency. It was hemic only when following some kind of hemorrhage. These, he said, were all the examples that his limited time admitted of for illustrating the value of the time-honored stethoscope, which, while other instruments might come and go, would always remain the readiest and most trustworthy tool of the general practitioner. There was a revolutionary tendency among some modern clinicians to dethrone the once all-powerful monarch of heart disease, the murmur, but this the speaker regarded as nothing less than treason. He might be called an old fogy, but he could not forbear stating his conviction that murmur was a very important element in the diagnosis of cardiac disease. It was true that a valvular lesion could be and frequently was demonstrated by physical signs other than the murmur, yet one felt disappointed if the murmur was not present to corroborate the other evidence.

The Electrocardiograph.—Dr. T. Stuart Hart said that, while the clinical use of the electrocardiograph was still in its infancy, it already gave promise of revealing some of the important secrets of the circulation. The string galvanometer of Einthoven, with which his records had been taken, was a large and expensive laboratory instrument which was not portable, and could be used only for such patients as could be brought within reach of its electrical attachments. The records he showed were from patients in the service of Professor James at the Presbyterian Hospital, and these at the time the records were taken were probably 300 or 400 feet distant from the instrument. The expense of the apparatus and the time and skill required for its manipulation would always confine its employment to the specialist, but this would not prevent the general practitioner from familiarizing himself with the records and their interpretation. In the future he would make use of the information thus obtained in the same manner as to-day he availed himself of the nitrogen partitions and other complicated determinations of the pathological chemist. The records were marvelous in their accuracy, and to the speaker their value as precise data of the delicate cardiac mechanism had been emphasized by the fact that when once one was familiar with the record of an unusual case he was able to pick out from a collection of miscellaneous records those obtained from this particular case (provided the circulatory conditions had not changed) without any other help than the *sui generis* character of the records. In the present state of one's knowledge, however, one was far from being able to interpret many of the records made. Thus far one had merely scratched the surface of the ground, but it was evident that underneath there were veins of precious metal awaiting further laborious excavation. The kind of practical problems which these observations were going to help one to solve were those connected with the functional capacity of the heart muscle, the nature and point of origin of the rhythmic impulses, the direction and rate of the propagation of these, and the factors

which modified them, which should therefore indicate the kind and value of therapeutic measures necessary to meet the conditions which one had thus learned to recognize. The difficult and complicated problem of blood-pressure was taken by Dr. Hart as an example. As one knew, the blood-pressure was the resultant of four main factors: the energy of the heart, the peripheral resistance, the elasticity of the arteries, and the volume of the circulating blood. The difficulty met with in any particular case of high or low pressure, and which had to be solved if one's therapeutic measures were to be of service, was to determine which of these factors was modified and to what extent. This was a matter upon which he believed the electrocardiograph would throw much light. He then cited an example of the problems upon which the observations made by means of this instrument had already thrown light, not simply of academic interest, but of practical clinical value. Auricular fibrillation was a condition met with in about 50 per cent of all cardiac cases ill enough to seek hospital care, and yet one which had not been recognized until records were obtained from the electrocardiograph. One of the diagrams presented showed great irregularity and a continuous wavy motion of the galvanometer string, even during the diastolic period. Animal experimentation had demonstrated that such a record was caused by the absence of gross auricular contraction, this having been replaced by fine fibrillary contractions of the muscle fibers of the auricle. The result of these was to throw into the bundle of His a great number of stimuli, which were propagated to the ventricle and, according to its condition at any particular moment, might or might not cause a ventricular contraction. Hence the entire absence of rhythm which had been called delirium cordis, complete irregularity, etc. Auricular fibrillation was characterized by a complete irregularity of the pulse, a ventricular form of venous pulse, and electrocardiographic records showing continuous oscillations and an absence of the P wave (representing the normal electrical variation during auricular contraction). With one's finger on the radial pulse one could make a fairly good guess as to whether or not one was dealing with a condition of auricular fibrillation, and a polygraphic record would give more certain evidence, but the electrocardiogram was the only means by which one could make the diagnosis conclusive. It was in these cases of auricular fibrillation that digitalis showed its greatest efficiency, and here again the electrocardiograph would record the effect of the medication and indicate to one the proper size of the dose. When the heart had been slowed to 50 or 60 a minute and the beats were coupled, presenting a form of bigeminus, it was well to reduce the amount of digitalis. The heart would then ordinarily become somewhat more rapid, 80 to 90 per minute, lose its bigeminal character, and assume a rhythm which might be called "a moderately complete irregularity." This was the point at which the damaged heart showed its best obtainable functional capacity, and digitalis should be continued in a dosage sufficient to keep it as near this as possible. It was probable that in these cases digitalis acted as a block to a part of the impulses coming from the auricle, and thus protected the ventricle, making its contractions fewer and also more efficient.

Examination of the Urine and Feces in Diseases of the Cardiovascular System.—Dr. JOHN J. CONNELLAN said that until quite recently the urine was the only secretion examined, and then simply to determine evidences of the different forms of nephritis. To-day special attention was paid to the determination of indican and indolactic acid. It was customary to examine the urine alone for evidence of intestinal putrefaction (the presence of indican). This procedure was misleading at the best, as the amount of indican was only the roughest index of the degree of putrefaction. Again, many authors claimed that indican was found in large amount in the urine in affections other than intestinal putrefaction; but he doubted this statement, as he did not believe that indican to any degree originated from the metabolism of proteid matter, but wholly from putrefactive processes in the lower intestines. In children it was commonly supposed that certain well-known signs were due to the presence of pinworms (oxyuris vermicularis); but in the examination of many hundred stools of children he had found these parasites in only two instances. What he did find was the presence of indol in at least 95 per cent of the cases, while the rest showed a highly fermentative condition. In many of them there were traces of albumin in the urine, and he believed further investigation would show that up to the fourth or fifth year of life the absorption of indol caused renal irritation. He therefore considered it reasonable to suppose that the cornerstone of many cases of cardiovascular disease was laid in the tender years of childhood. Having described the characteristics of normal stools both in adult and infant life, he stated that the whole problem regarding the treatment of indicanuria could be reduced to the reaction of the alimentary tract and the character of the food ingested. The natural presumption was that bacteria should, if possible, be eliminated; but the fact was that they were a necessary factor in the complex economy of the intestine. Anaerobic or putrefactive bacteria had the power to disintegrate proteid substances, with the resulting formation of several mildly toxic agents: mainly indol, skatol, and phenol. The putrefaction of proteids without the action of anaerobes was impossible. Indol, when found in feces, was in the raw state, but in the urine its character was radically changed by chemical action. It was absorbed through the portal circulation and, by its combination with sulphuric acid excreted by the hepatic cells, an indoxyl sulphate was formed. Entering the blood stream, this became, through the action of the potassium of the blood, an indol potassium sulphate, and it was thrown off through the kidneys as such. There was a wide difference of opinion as to the toxicity of indol in the blood stream, but the speaker believed that it was only a mild toxin, which could not by itself set up the severe symptoms of auto-intoxication. If, however, it was retained in the blood, as in cases of chronic interstitial nephritis, it became more toxic than when its elimination was not retarded. His contention was that there was closely allied toxin, as yet not demonstrated by chemical tests, which was absorbed with indol from pronounced putrefactive tracts and which produced the clinical picture seen in auto-intoxication. In examining over 40,000 specimens of urine for Dr. Bishop he had found indican absent in only one of the primary examinations of his chronic cases. Dr. Bishop made the point that where intestinal putrefaction existed alkaline purges or laxatives were contraindicated. This seemed radical, but, when it was realized that all such alkaline agents would either change the reaction in the alimentary tract to a degree of alkalinity or increase the same if that reaction already existed, it could readily be seen that by giving alkalis, and thus promoting the growth of putrefactive bacteria and inhibiting or destroying the development of the acid-producing group, one was simply "adding fuel to the fire." Recently he had examined a urine which was so loaded with indican that it was impossible to throw it all down, while the feces of the same subject showed a marked alkaline reaction. Bacteria formed at least seven-eighths of the residue. Bouillon and agar showed very few colonies in comparison with the normal stool. The anaerobic cultures showed an enormous growth, and the gas volume tube, after thirty hours, showed 136 per cent of putrefactive gas volume. On investigating the history of this patient he found that

he had been given alkaline purges, in small doses, for several days. Cardinal points in the treatment of intestinal putrefaction, from the laboratory viewpoint, were diet and exercise, with resulting oxidation and reaction of the tract. After many failures to find with the use of gas tubes an agent that without causing a fermentative gas would inhibit the growth of putrefactive bacteria, and at the same time reach the lower intestine almost unchanged, Dr. Connellan had concluded that the use of sugar of milk in moderate doses would secure the desired results. In a recent article Kendall advocated the employment of this agent in intestinal diseases in children, with the idea in view of preventing or destroying putrefactive bacteria. The conclusions reached were as follows: Indican in the urine resulted from intestinal putrefaction, not from the metabolism of proteid matter; in doubtful cases, or to get a correct idea of the degree of intestinal putrefaction, the feces should be examined for indol, and a gas tube used to estimate the amount of putrefactive gas; the urine of children should be frequently examined for indican, especially after diseases which caused renal irritation; in all diseases of the renal tract the presence of indoxyl in the blood stream was detrimental; intestinal putrefaction could be treated only by changing the reaction of the tract to such a degree of acidity that putrefactive bacteria would grow or flourish; where an intestinal putrefaction existed all alkaline cathartics should be prohibited; the use of tablets of dead bacteria to overcome the putrefactive bacteria was of very questionable value, though live cultures of antagonistic bacteria were believed to be of service.

Heart Therapeutics and the Individual Patient.—Dr. James J. Walsh said that nothing had been clearer at all times since men began to make observations on themselves than the influence of thought and emotion upon the heart; and the recognition of the changes in its action produced by such causes and the manifestly important place of the organ in the economy led many in former times to believe that the heart itself was the seat of the emotions. It was thus made responsible for phenomena which occurred quite independently of it, but happened to affect it deeply. In all cases of heart disease it was evidently of the greatest importance to give the patient just as much assurance of mind as possible. In many instances there was really very little occasion for alarm. Thus it was perfectly possible to have a loud murmur without any serious affection of the heart. Indeed, a loud murmur was usually a sign of a strong, vigorous heart muscle, and so long as this remained healthy the prognosis was good. Often the disappearance of murmurs was of much graver import than their loudness. Gerhardt used to teach that if the apex beat were displaced there was probably something serious the matter with the heart or some neighboring organ, while if the apex beat was in place little trouble was to be apprehended. When serious symptoms were present nothing had so great a tendency to restore compensation as reassurance of the patient. The physician should learn to use this kind of mental therapeutics deliberately; not to do so was to neglect an important feature of therapy. It could be employed improperly, but from the abuse of a thing no argument against its legitimate use held in logic. Through the mind a great deal could be done to calm the heart, and the use of this calming influence was probably a better remedy than any other. Certainly there were no idiosyncrasies against it, and upon some individuals its effect was most potent. One was sometimes prone to think, on hearing of marked benefit following shortly after the administration of digitalis, that the mental influence was more important than anything else, especially when one recalled the fact that the physical effects of digitalis were not manifest under twenty-four hours. The point under consideration had been recognized by physicians of all periods, and emphasized by every distinguished cardio-therapeutist in recent years. It seemed to the speaker, however, that one sometimes forgot how much the patient's mind counted in such cases, and that there were many in whom the mental influence over the heart was much greater than in others. These would not be improved, no matter how powerful the remedies employed, unless their minds were set at rest. In confirmation of the views expressed he then quoted from the writings of two eminent authorities, Broadbent and Mackenzie.

Some Notes on Mackenzie's Work.—Dr. Victor E. Sorapure, who had met Mackenzie personally, gave an interesting account of his manner of life and an appreciation of his eminent contributions to medical science. So far from finding his work barren of therapeutic results, as was often claimed, he believed that the principles of treatment he had laid down were so rational and so universally applicable that they must influence every school of thought. In concluding his estimate of the man the speaker recalled the fact that, like the true general practitioner that he was, Mackenzie had not neglected any organ or system in his observations and studies, for if he had never published his great works on the heart and pulse his work on the interpretation of symptoms would be sufficient to claim for him the gratitude of his generation.

Philadelphia County Medical Society.

At a stated meeting held May 11 Dr. Hilary M. Christian presented a communication entitled "A Clinical Study of Cases of Syphilis Treated with Salvarsan." He reported the results obtained in fifty-seven cases of syphilis of varying stage and degree treated by means of intragluteal injections of arsenobenzol, without complication and with excellent results in thirty-two of the cases. In the remaining twenty-five cases the results were unsatisfactory or disappointing. The importance of continuing treatment with mercurials following the employment of arsenobenzol was emphasized. Dr. Guthrie McConnell read a paper entitled "The Pathology of Neuralgia." He pointed out the impossibility of distinguishing between a neuralgia without obvious lesion and an actual inflammation of a sensory nerve, causing pain. In all instances, however, there must be some change in the nerve or its ganglion occasioning the symptoms. Dr. James Hendrie Lloyd read a paper entitled "The Neurology of Neuralgia." He dwelt on the relation of so-called neuralgia to numerous varied conditions, relief from which must first be afforded before permanent cure of the painful state can be expected. He related a case of trigeminal neuralgia in which relief was afforded for a year by division of the sensory root of the Gasserian ganglion following a period of relief of a year and a half after resection of several branches of the fifth nerve. Dr. Ernest Laplace discussed "The Surgery of Neuralgia," speaking first of nerve-stretching, next of resection, and then of avulsion of nerves with plugging of their orifices of exit. Should these measures fail, resort may be had to resection of the Gasserian ganglion or division of its sensory root. He referred to a case of trigeminal neuralgia in which many operations had been performed with only temporary relief, and in which after death a tumor of the cerebello-pontile angle was found. Dr. W. S. Newcomet spoke of the "Röntgenology of Neuralgia," showing how painful conditions in the distribution of the branches of the inferior maxillary nerve might by means of fluoroscopic or radiographic examination be shown to arise as a result of displaced or unirrupted teeth, or of the presence of fillings or fragments of dental instruments, and he made it clear that relief could only follow removal of the disturbing factors.

Dr. A. A. Eshner discussed "The Treatment of Neuralgia by Alcoholic Injections." He pointed out that the treatment of neuralgia with various forms of injection, sterile water, saline solution, drugs in solution, anesthetic or otherwise, had long been practised, while it is only within a period of ten years that deep, intraneural injections of 70, 80, or 90 per cent. alcohol had been made. The results have been satisfactory in a large number of instances. The method has been employed particularly in the treatment of tic douloureux. The fifth nerve may be approached for this purpose either from the cavity of the mouth behind the last molar tooth or from the side of the face. The object is to reach the first division of the nerve in the sphenoidal sinus, the second division in the round foramen, and the third division in the oval foramen. Anesthesia, local or general, is employed by some, although rejected by most. The injection is attended with a sense of burning and tingling, but it is soon followed by relief of pain. Anesthesia in the distribution of the nerve treated may last for a week or more. Sometimes several injections are required in the course of a week or two. Often the freedom from pain persists for weeks or months or even a year or more. When it returns the injection may be repeated.

College of Physicians of Philadelphia.

At a stated meeting held December 7 Dr. Astley P. C. Ashhurst gave an "Exhibition of Three Cases of Severe Types of Infantile Paralysis Cured by Operation (Arthrodesis in Two Cases and Tendon Transplantation in One Case)." Operation was performed when deformities existed in degree and chronicity not amenable to other means of treatment and resulted in restoration of function of disabled parts and removal of the necessity for wearing braces and the like. Dr. James Tyson presented, on behalf of Mrs. Susan Parrish Wharton, a portrait of Dr. Joseph Parrish, who was born in 1779, was elected a fellow of the college in 1810, and died in 1840. He was a distinguished practitioner of his time, and while never connected with a medical college did considerable medical teaching to private students. Dr. Ralph Pemberton presented a communication entitled "A Study of Myotonia Atrophica, with the Report of Two Cases and the Exhibition of One." The disorder is a muscular dystrophy, with inability at once to overcome or release a performed motor act. Careful metabolic studies demonstrated a deficient kreatinin output, without apparent change in the calcium balance. It was suggested that in the metabolic derangement resides the most important criterion for differentiating various disorders of the muscular system. Drs. Wm. G. Spiller and Paul V. Anderson presented a communication entitled "Pellagra, with a Study of the Nervous Tissues," reporting the results of an historical study of the nervous system in two cases of pellagra carefully observed clinically. There was found a widespread degeneration of the nerve cells of the brain and cord, and no indication of systemic distribution, and accordingly it was concluded that the noxious agent must be toxic or infectious.

Toxic Dermatoses Due to Injection of Salvarsan.—Vincenzo Fisicella records two cases of toxic skin troubles resulting after injection of salvarsan. The arsenical eruptions are numerous and among them is herpes zoster. In one of the authors patients this eruption with its accompanying neuralgia appeared after the injection of salvarsan, lasted for a short time, and then rapidly disappeared. In the other patient the eruption was characterized by erythema in the beginning, marginate and circinate ,then slowly took on the characterisie of pityriasis maculata and circinata. After a second arsenical treatment with Fowler's solution taken some time later the same eruption recurred. Perhaps in this case the salvarsan had not yet been quite eliminated at the time of the Fowler's solution treatment.—*La Riforma Medica.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

State Board of Medical Examiners of South Carolina

June, 1911.

general anatomy (Junior Curriculum).

1. Name group of bones that make up lower extremity.
2. Name the seven muscles of the orbital region.
3. Name branches of brachial artery.
4. Name the five veins of the neck which return the blood from the head and face.
5. Show by drawing the regions of abdomen.

surgical anatomy (Senior Curriculum).

1. Why is the shoulder joint most liable to dislocation?
2. Where is congenital dislocation most often found? How diagnosed?
3. Name the arteries met with in lateral lithotomy.
4. Where in the appendages does extrauterine pregnancy most commonly occur?
5. In deafness, after history of injury, how by tuning fork would you determine whether the nerve itself was destroyed or was due to some lesion of auditory apparatus?
6. Which of the vessels of the arterial system is most frequently the seat of disease, and what part or portion?
7. Why, when, and where would you make lumbar puncture?
8. Symptoms of irritation of phrenic nerve? What would be the consequence of bilateral paralysis of this nerve? Fracture dislocation of what cervical vertebra would produce this paralysis?
9. When and why would you use the Trendelenburg position? When and why would you use Fowler's position?
10. Of what surgical importance is the location of the lower part of the brachial artery in venesection?

physiology (Junior Curriculum).

1. Name the varieties of cartilage and state where each is found.
2. What produces the second sound of the heart and what events in the heart's action are coincident with it?
3. Give the varieties of secreting glands and examples of each.
4. Give the functions of the 10th cranial or pneumogastric nerve according to its distribution.
5. What is the purpose of respiration and what changes take place in the respired air?

hygiene (Senior Curriculum).

1. Name the common breeding places of house flies. Tell how best to destroy flies, and name diseases transmitted by them.
2. How is the hookworm propagated? How does it gain entrance into the human system, and how is the disease spread?
3. Given case of typhoid fever, describe proper precautions to prevent spread of disease.
4. How long is it necessary to quarantine in scarlet fever, measles, diphtheria, and smallpox respectively?
5. What would constitute an ideal sleeping room?
6. Describe a sanitary rural privy.
7. In an inspection of public school children, what diseases or abnormalities are commonly found which ought to be corrected and, briefly, why?
8. In scabies in school children what would you do?
9. Given an infant 6 months old, emaciated, anemic, one or more joints swollen and painful, fed on malted milk exclusively, give diagnosis, cause of condition, and proper feeding to restore to health.
10. Give diet in diabetes, chronic nephritis, rheumatism, phthisis, and why.

chemistry (Junior Curriculum).

1. Define an element, an atom, a molecule, and chemical force.
2. Give the chemical name and formula for each of the following: Caustic potash, saltpeter, Epsom salts, lime, and calomel.
3. Differentiate dialysis and osmosis.
4. How is formaldehyde prepared? In what forms is it used as a disinfectant?
5. What is electrolysis? Give example. Give the forms of electricity in clinical use.

PRACTICAL URANALYSIS, MICROSCOPY, AND TOXICOLOGY.

(Senior Curriculum.)

1. What is the reaction of normal urine? To what is it due?
2. What is a urinometer? Give specific directions for its use. State how it may aid in diagnosis.
3. Give concisely the technique of a chemical examination of the urine for life insurance.
4. Give concisely the technique of a microscopic examination of the urine.
5. State how you would examine for pus in the urine if you had no microscope.
6. What do you understand by a corrosive poison? How soon after taking will symptoms develop?
7. How does a corrosive poison differ from an irritant poison? Give an example of each.
8. Give symptoms and chemical and physiological antidote for digitalis poisoning.
9. Give symptoms and chemical antidote for acute acetate of lead poisoning.
10. How do chemical and physiological antidotes differ in action?

MATERIA MEDICA (Junior Curriculum).

1. Give two antipyretics.
2. Give two hydragogue cathartics.
3. Give two cholagogue cathartics.
4. Give two diuretics.

Give dose to effect of each of the above drugs.

5. Give dose and physiological effect of (*a*) morphine, (*b*) strychnine, (c) atropine, (*d*) pilocarpin.

THERAPEUTICS (Senior Curriculum).

In treating the following diseases, give dose, frequency, and physiological effect of drugs used; if other than drugs, method with physiological effect; 1. acute bronchitis; 2. chlorosis; 3. cholera infantum; 4. intestinal toxemia of infants or green diarrhea; 5. laryngismus stridulus; 6. puerperal eclampsia; 7. scabies; 8. lumbago; 9. uremic poisoning; 10. acute lobar pneumonia.

PRACTICE OF MEDICINE.

1. What symptoms would determine you in arriving at a diagnosis of: (*a*) grand mal, (*b*) petit mal, (*c*) Jacksonian epilepsy?
2. What are the clinical symptoms of the conditions which are liable to follow lobar pneumonia?
3. A man 40 years old has a blood-pressure of 180. Discuss its clinical significance.
4. What are the symptoms of carcinoma of the liver?
5. Describe a case of acute follicular tonsillitis, stating the diseases with which it might be confounded and their diagnostic differences. Give treatment you would use for a case of that affection.
6. Give etiology, symptoms, and treatment of parenchymatous nephritis.
7. In what diseases may hemorrhage from the bowels occur? What assistance in diagnosis may be obtained from inspection of the stools?
8. Discuss poliomyelitis: (*a*) Etiology, (*b*) premonitory symptoms, (*c*) symptoms, (*d*) prognosis, (*e*) treatment, including precautions, if any, you would take to prevent spread of the disease.
9. In what diseases is lobar pneumonia most liable to occur as a complication? What symptoms would cause you to suspect such a complication existed?
10. In June it is necessary to feed artificially an infant 8 months old; give explicit directions so that an intelligent mother could follow your instructions.

OBSTETRICS.

1. Define hysterectomy, and state its indications.
2. How is an ovarian tumor to be diagnosed from pregnancy?
3. What may result from laceration of the perineum?
4. Describe the symptoms and management of an incomplete abortion.
5. Describe the human embryo during the second month.
6. Give treatment of eclampsia.
7. How is a posterior position of the occiput to be diagnosed and managed?
8. What are the dangers of a breech presentation, and how should an impacted breech be managed?
9. Diagnose and give mechanism and delivery in face presentation.
10. How would you treat a case of placenta prævia when hemorrhage occurs prior to full term? (*b*) How would you treat a case of postpartum hemorrhage?
11. Describe (*a*) funic souffle, (*b*) uterine souffle, (*c*) ballottement, (*d*) Hegar's sign, (*e*) Braxton Hick's sign, (*f*) Rasch's sign, and (*g*) Jacquemier's sign.
12. What would lead you to suspect extrauterine pregnancy?
13. Give two symptoms of toxemia of pregnancy with treatment of each.

Answer only ten questions.

SURGERY.

1. Define anesthesia. Mention two favorite general anesthetics. What can you say as to their relative merits?
2. Describe intubation of the larynx (O'Dwyer's operation).
3. Mention several steps in performing perineal section (external perineal urethrotomy).
4. What is phimosis? What is the treatment? Describe the operation.
5. Acute cystitis; give symptoms and treatment.
6. Describe ligation of the radial artery in the upper third.
7. What are fractures? Mention different varieties. How would you diagnose fracture? What are the indications in treating a fracture?
8. Dislocation of the elbow joint: In backward dislocation of both bones what would be the symptoms? The treatment?
9. Mention the several steps in amputating the forearm through the middle third.
10. In burns and scalds what are the local symptoms? The constitutional symptoms? What the local treatment? The constitutional treatment?

BACTERIOLOGY AND PATHOLOGY (Junior Curriculum).

1. Name three pyogenic bacteria. Where are they found in health? Where in disease? And give usual method of staining.
2. Describe the diphtheria bacillus. How would you obtain a specimen for examination, and how would you determine when to release a patient from quarantine?
3. Describe the pathology of scarlet fever and give the usual complications.
4. How are tumors usually classified? Describe a myoma and an epithelioma.
5. Give the pathology of mitral insufficiency with loss of compensation.

MEDICAL JURISPRUDENCE (Senior Curriculum).

1. In gunshot wounds differentiate point of entrance from point of exit and give medicolegal significance of position of wound and direction of wound.
2. Describe the post-mortem findings in phosphorus poisoning; from what industrial source is poison usually obtained? Give antidote.
3. Give immedite and remote effects of concentrated lye poisoning. To what class of poisons does it belong?
4. Describe in detail the healing process in a case of burn.
5. In suspected case of criminal abortion how would you determine whether pregnancy had existed?
6. Give the most important medicolegal question arising in the disposition of property by will.
7. State order in which decomposition usually takes place in a dead body. What conditions hasten it, what retard it?
8. What are the post-mortem findings in drowning?
9. Differentiate a stillborn infant, full term, from one dying a few hours after birth.
10. Mr. A., past middle life, retires at 9 P. M., apparently in good health, and is found dead in bed at 7 A. M. with rigor mortis well marked. Give probable hour of death and state what diseases might have caused death.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF SOUTH CAROLINA.

June, 1911.

GENERAL ANATOMY.

1. Os innominatum (ilium, ischium, pubis); femur; patella; tibia; fibula; tarsus (os calcis, astragalus, cuboid, scaphoid, internal cuneiform, middle cuneiform, external cuneiform); five metatarsals; fourteen phalanges.
2. *Seven muscles of orbital region:* Levator palpebræ superioris, rectus superior, rectus inferior, rectus internus, rectus externus, obliquus superior, and obliquus inferior.
3. *Branches of brochial artery:* Superior profounda, inferior profunda, nutrient, anastomotica magna, and muscular.
4. *Five veins of the neck which return the blood from*

the head and face: External jugular, posterior external jugular, anterior jugular, internal jugular, and vertebral.

5. See Cunningham's "Anatomy" (1909), page 1046; or Gray's "Anatomy" (1910), page 1242.

SURGICAL ANATOMY.

1. *The shoulder joint is most liable to dislocations,* on account of: (1) The shallowness of the glenoid fossa; (2) the large size of the head of the humerus; (3) great freedom of motion; (4) the thinness and laxity of the capsular ligament; (5) the joint depends on the surrounding muscles for its strength; (6) the long leverage of the arm; (7) its exposure to violence.

2. Congenital dislocation is most often found at the hip joint; it gives rise to extreme lordosis, and a waddling gait is noticed when the child attempts to walk.

3. *The arteries met with in lateral lithotomy:* Transverse perineal, external hemorrhoidal (artery of the bulb and pudic artery).

4. Extrauterine pregnancy most often occurs in the Fallopian tube.

5. The distinction between ordinary deafness and the nervous form is made by testing with watch or tuning fork. "If the ticking of a watch or the vibrations of a tuning fork are heard faintly or not at all when held at varying distances from the ear (aerial conduction), but become distinctly audible when the watch or the handle of the fork is placed in contact with the skull or mastoid process (bone conduction), the deafness is of the ordinary variety and due to aural disease. If, on the other hand, watch and fork are heard indistinctly or not at all, both in contact and at a distance, the deafness is due to some lesion of the nerve or its connections. In the first case the nerve is normal and can appreciate vibrations brought by the bone, while, through some fault in the mechanism, aerial vibrations are not transmitted to the nerve endings. In the second case the nerve is at fault and cannot appreciate vibrations, no matter how well they may be conducted."—(Butler's *Diagnostics of Internal Medicine.*)

6. The aorta, more especially the arch, is, of all the vessels of the arterial system, most frequently the seat of disease.

7. *Lumbar puncture* may be made for diagnostic purposes, therapeutically, or for administration of spinal anesthesia. The puncture is made below the second lumbar vertebra, usually between the third and fourth lumbar spines.

8. Irritation of the phrenic nerve may cause hiccough and persistent cough. Bilateral paralysis of the phrenic nerve causes death from paralysis of the diaphragm. Fracture dislocation of the third cervical vertebra will produce this paralysis.

9. In the lymphatics of the peritoneum, those of the diaphragm are more rapid in absorption than those of the pelvis.

To stimulate, the patient should have the foot of his bed raised (*Trendelenburg's position*), so that the fluid (salt solution) may be conveyed more readily to the diaphragm, where absorption is more rapid.

To retard the too rapid absorption of pus in the abdominal cavity, the head of the bed should be raised (*Fowler's position*) so that drainage may be directed toward the pelvis, where absorption is slower.

10. "The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery." (Gray.)

PHYSIOLOGY.

1. *Varieties of cartilage.* 1. *Hyaline;* found in the joints, at the ends of the ribs, in the nose, trachea, bronchi, and larynx. 2. *Yellow elastic;* found in the external ear, Eustachian tube, epiglottis, and in cartilages of Santorini and Wrisberg. 3. *White fibrous;* found in intervertebral substance, symphysis pubis, and larynx.

2. The second sound of the heart is caused by the vibration due to the closure of the semilunar valve; coincident with it are: the commencing dilatation of the ventricles, opening of the auriculo-ventricular valve, continuation of the auricular diastole, and closing of the semilunar valves.

3. I. SIMPLE GLANDS.—Duct undivided.

(*a*) *Simple tubular*—Undilated at end—*e.g.* Lieberkühn's follicles, sweat, and many gastric glands.

(*b*) *Simple acinous (alveolar or saccular.)*—Dilated at end—*e.g.* some sebaceous glands (rare).

II. COMPOUND GLANDS.—Duct divided.

(*a*) *Compound tubular.*—Branched elongated tubes, no tubes, no acini—*e.g.* most gastric glands.

(*b*) *Compound acinous or alveolar (racemose glands),* branched duct with saccular acini on terminal branches—*e.g.* salivary, sebaceous, and Meibomian glands; the mucous glands of the mouth, tongue, palate, pharynx, nose, esophagus, and respiratory tube.

(*c*) *Acino-tubular.*—Branched duct, with elongated narrow acini on terminal branches—*e.g.* Brunner's glands.

(From Cunningham's *Anatomy.*)

4. *Functions of the pneumogastric nerve:* "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc." (Kirkes' *Physiology.*)

5. The purpose of respiration is to provide oxygen to the blood and tissues, and to eliminate carbon dioxide.

	EXPIRED AIR.	INSPIRED AIR.
Oxygen	16.6 per cent.	21 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide...	4.4 per cent.	0.04 per cent.
Other gases.....	Often present.	Rare.
Watery vapor....	Saturated.	Variable.
Temperature	That of body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present.
Dust	None.	Always present.

HYGIENE.

1. Common breeding places of house flies: Manure heaps, privy vaults, garbage pails, etc. Flies are best destroyed by being caught on fly papers or in fly traps, and then burned. *Diseases transmitted by flies:* Typhoid, cholera, plague, tuberculosis, dysentery, anthrax, and intestinal parasites.

2. See French's "Practice of Medicine" (1910), page 505; or Osler's "Practice of Medicine" (1909), page 44.

3. See French's "Practice of Medicine" (1910), page 107; or Osler's "Practice of Medicine" (1909), page 96.

4. PERIOD OF QUARANTINE for: *Scarlet fever:* till the patient is quite free from sore throat or discharges of any kind, and the desquamation has entirely disappeared; generally six to eight weeks.

Measles: About one month from onset of symptoms provided no sequelæ are present, and no discharges persist.

Diphtheria: till the patient is free from all signs of congestion or rhinitis, and continued bacteriological examination is persistently negative.

Smallpox: till all crusts or scabs have entirely disappeared.

5. The sleeping room should be as large as possible, with the maximum of sunshine and fresh air; it should face the south, or east, or southeast, and should contain no hangings, and have as few "dust-catching" contrivances as possible; it should not lead into a bathroom.

6. *A sanitary rural privy* consists of a "small watertight pit, not drained but roofed over to exclude rain, and so arranged that the excreta and ashes become thoroughly mixed. For this purpose either the ashes must be thrown in through the closet seat, which may be hinged so as to be lifted *en masse,* or else a "shoot" or sloping slab must conduct one or the other to a common point. The floor should be smooth, and raised a few inches above the level of the adjoining ground.

"The contents ought to be removal at fixed short intervals, and the work should be done at night or early in the morning so as to minimize the nuisance." (Whitlegge and Newman.)

7. Infectious diseases, such as measles, scarlet fever, smallpox, chicken pox, mumps, diphtheria; adenoids; strabismus, trachoma; spinal curvature; pediculosis, scabies, ringworm.

8. *The treatment of scabies* "consists in a protracted bath with soap and hot water, followed by the application of sulphur ointment (3i to 3i) or other parasiticide every night for one week. In the meantime the bed linen and underclothing should be sterilized by heat. At the end of

a week another bath should be taken and some sedative ointment or lotion should be prescribed. Sulphur may be substituted by beta-naphthol, balsam of Peru, styrax, tar, staphisagria, etc."—(Gould and Pyle's *Pocket Cyclopedia.*)

9. The infant, probably, has scurvy; due to improper food. This proprietary food should be stopped and the infant be fed on fresh cow's milk, modified if necessary. The addition of fresh fruit juice (orange) may be of value.

10. See French's "Practice of Medicine" (1910), pages 974, 923, 932, 230, and 399; or Osler's "Practice of Medicine" (1909), pages 420, 694, 700, 226, and 356.

CHEMISTRY.

1. An *element* is a kind of substance out of which we cannot, by any known means, get dissimilar substances.

An *atom* is the smallest part of an element that can enter or leave a chemical reaction.

A *molecule* is the smallest portion of matter (element or compound) which can exist in a free state.

Chemical force is that force by which atoms are held together in the molecule.

2. Caustic potash is potassium hydroxide, KHO; saltpeter is potassium nitrate, KNO_3; Epsom salts is magnesium sulphate, $MgSO_4$; lime is calcium oxide, CaO; calomel is mercurous chloride, Hg_2Cl_2.

3. *Dialysis* is the process of separating substances from a mixture by placing the latter in a vessel with porous walls and immersing it in water, when the more diffusible substance passes through the porous wall. This latter process is called *osmosis.* Substances which readily pass through this porous membrane are called *crystalloids;* those which do not are called *colloids.*

4. Formaldehyde is prepared by the dry distillation of calcium formate:

$$Ca(H\cdot COO)_2 = CaCO_3 + H\cdot COH.$$

It is used as a disinfectant under the forms of: Formaldehyde, paraform, trioxymethylene, formalin, formol.

5. Electrolysis is the process of electrical conduction accompanied by the separation of the constituents of the electrolyte or the decomposition of a chemical compound by passing an electric current through it. The primary products of electrolysis are called ions; those which separate at the positive electrode or anode are called anions; those which separate at the negative electrode or cathode are called cations. A solution of sodium chloride contains NaCl, but it also contains the cation Na and the anion Cl; and the action of the electric current is to separate these ions (which are already liberated) at the respective electrodes. It is supposed that the hydrogen and metallic ions are charged with positive electricity, and the hydroxyl and acid-residue ions are charged with negative electricity; hence the former are attracted to the cathode and the latter to the anode.

Forms of electricity in clinical use are: Electricity by friction, by induction, by chemical action, and by magnetism.

PRACTICAL URANALYSIS, MICROSCOPY, AND TOXICOLOGY.

1. The reaction of normal urine is acid; due to acid sodium phosphate.

2. A *urinometer* is a form of hydrometer used for determining the specific gravity of the urine. It consists of a cylinder and a spindle. The graduation on a urinometer is so constructed that the spindle sinks to the zero point when it is immersed in water at a given temperature. The denser the fluid into which the spindle is immersed the higher it rises. The ordinary urinometer is graduated from 0 or 1000 to 60 or 1060.

To use the urinometer: "The cylinder should be without pouring lip, of such depth that the urinometer may be completely immersed, and of a diameter double that of the wide part of the urinometer. Hold the cylinder in an inclined position and pour into it urine to within 2 cm. of the top. Set it upright, float the urinometer in the urine, and add more urine until the level "heaps" above the rim of the cylinder. Now bring the eye to about the level of the top of the cylinder, and, seeing that the urinometer does not touch the wall of the cylinder, read off the specific gravity at the *highest* point where the liquid, drawn up by capillary attraction, cuts the graduation of the urinometer."—(Witthaus' *Urinalysis,* etc.)

The specific gravity of normal urine varies from about 1015 to about 1025. An *abnormally high* specific gravity may be found in: Diabetes mellitus, fevers, and chronic parenchymatous nephritis.

Low specific gravity of the urine may indicate: Diabetes insipidus, chronic interstitial nephritis, contracted kidney, some nervous disorder, albuminuria, hysteria, or some nervous disorders, or the ingestion of an abnormal amount of fluids.

3 and 4. See French's "Practice of Medicine" (1910), pages 1233, etc.

5. *Pus* in the urine: Acidify the urine with acetic acid, then filter it, and treat the filter with a few drops of freshly prepared tincture of guaiacum; a deep blue color denotes the presence of pus.

6. A corrosive poison is a substance capable of producing death or serious bodily harm by its chemical action upon a tissue with which it comes in direct contact. Symptoms begin to develop immediately.

7. An irritant poison has to be in solution in the blood before it begins to take effet. Sulphuric acid is a corrosive; arsenic is an irritant.

8. DIGITALIS POISONING. *Symptoms:* Nausea and occasionally vomiting. Sometimes colic and diarrhea. After two or three hours marked diminution in the frequency of the pulse, which may fall to 40 or even 25. Dyspnea, attended by a sense of oppression in the chest and coldness of the extremities. Headache, vertigo, and tendency to sleep. Usually attacks of syncope occur, provoked sometimes by the slightest movement of the patient.

Chemical antidote: Tannic acid.

Physiological antidote: Aconite and opium.

9. LEAD ACETATE POISONING. The *symptoms* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions; and tetanic spasms."

The *treatment* consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube."—(Witthaus' *Essentials of Chemistry.*)

10. ANTIDOTES are classified as: (1) *Chemical antidotes,* which act by uniting chemically with the poison and thus converting it into a harmless or insoluble compound. *Example:* Albumin, in mercurial poisoning; sodium sulphate, in carbolic poisoning.

(2) *Physiological antidotes,* which act by combating one (or more) of the physiological actions of the poison. *Example:* Opium will counteract the dilated pupil caused by belladonna.

MATERIA MEDICA.

1. *Two antipyretics:* Aconite, dose 5 to 10 min. of the tincture; and acetanilid, dose, gr. iv.

2. *Two hydragogue cathartics:* Elaterin, dose of the trituration, about 1/10 gr.; and potassium bitartrate, dose ½ to 1 oz.

3. *Two cholagogue cathartics:* Podophyllin, dose of the resin, gr. ½ to j; and aloes, dose 1 to 5 gr. of the extract.

4. *Two diuretics:* Potassium acetate, dose 30 to 60 gr.; and potassium citrate, dose 15 to 30 gr.

5. MORPHINE. *Dose* of sulphate, gr. ⅛ to ½. *Physiological action:* It is analgesic, hypnotic, diaphoretic, narcotic, a respiratory and cardiac stimulant (later a depressant), it checks most secretions (not perspiration), it stimulates the brain, and contracts the pupil.

STRYCHNINE. *Dose* of sulphate, gr. 1/64 to 1/32. *Physiological action:* Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension, stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes.

ATROPINE. *Dose* of sulphate, gr. 1/250 to 1/60. *Physiological effects:* Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

PILOCARPINE. *Dose* of hydrochloride, gr. ⅛ to ½. It stimulates secretory nerves and involuntary muscles, is a myotic, nervous depressant, and sudorific.

THERAPEUTICS.

1. See French's "Practice of Medicine" (1910), page 666; or Osler's "Practice of Medicine" (1909), page 603.

2. See French's "Practice of Medicine" (1910), page 523; or Osler's "Practice of Medicine" (1909), page 730.

3. See French's "Practice of Medicine" (1910), page 804; or Osler's "Practice of Medicine" (1909), page 511.

4. See French's "Practice of Medicine" (1910), page 799; or Osler's "Practice of Medicine" (1909), page 509.

5. See French's "Practice of Medicine" (1910), page 663; or Osler's "Practice of Medicine" (1909), page 599.

6. See OBSTETRICS, 6.

7. For *scabies*, sulphur or betanaphthol (3j to ℥j of lard) may be used to kill the parasite.

8. See French's "Practice of Medicine" (1910), page 953; or Osler's "Practice of Medicine" (1909), page 397.

9. See French's "Practice of Medicine" (1910), pages 909 and 930; or Osler's "Practice of Medicine" (1909), page 702.

10. See French's "Practice of Medicine" (1910), page 177; or Osler's "Practice of Medicine" (1909), page 189.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), pages 1163 and 1166; or Osler's "Practice of Medicine" (1909), pages 1060, 1062, and 1063.

2. See French's "Practice of Medicine" (1910), page 169; or Osler's "Practice of Medicine" (1909), page 180.

3. This *high blood-pressure* may be due to various conditions. "In *chronic interstitial nephritis* the elements of arteriosclerosis, high peripheral resistance, and increased heart energy bring about high readings. In abnormal nervous excitement temporary high pressure may be observed. In secondary myocarditis with *associated arteriosclerosis*, the uremic state, lead poisoning, gout, cerebral hemorrhage, and sometimes in *parenchymatous nephritis or early acute nephritis* high readings are present."—(Greene's *Medical Diagnosis.*)

4. See French's "Practice of Medicine" (1910), page 858; or Osler's "Practice of Medicine" (1909), page 569.

5. See French's "Practice of Medicine" (1910), page 735; or Osler's "Practice of Medicine" (1909), page 445.

6. See French's "Practice of Medicine" (1910), pages 910 and 918; or Osler's "Practice of Medicine" (1909), page 692.

7. "It is evident that a decision as to the origin of the blood in a given case can be reached only by a careful consideration of the history and symptoms, as well as a painstaking physical examination. It may be of service to bear in mind that the most frequent causes of hemorrhage from the bowel are hemorrhoids, typhoid fever, colitis, and cancer of the colon; that the most frequent causes of *large* intestinal hemorrhages are typhoid fever, portal engorgement from disease of the heart or liver, hemophilia, purpura hæmorrhagica, and rupture of an aneurysm; that the most frequent causes of *small* hemorrhages from the bowel are hemorrhoids, injury to the rectum or a rectal fissure by the passage of feces, ulceration (syphilitic or cancerous) of the rectum, and intussusception in infants and children. The extent of an intestinal hemorrhage, and on occasion its occurrence before appearing in the stools, may be judged by the constitutional symptoms, which are those of internal hemorrhage."—(Butler's *Diagnostics of Internal Medicine.*)

And see French's "Practice of Medicine" (1910), page 1228.

8. See French's "Practice of Medicine" (1910), page 1068; or Osler's "Practice of Medicine" (1909), page 914.

9. See French's "Practice of Medicine" (1910), page 92; or Osler's "Practice of Medicine" (1910), page 84.

10. "The bottle should be thoroughly cleansed with borax and hot water (one tablespoonful of borax to a pint of water) and boiled before using. The nipple should be turned inside out, scrubbed with a brush, using hot borax water. The brush should be used for no other purpose. The bottle and nipple should rest in plain boiled water until wanted. Never use grocery milk. Use only bottled milk which is delivered every morning. From May 1 to October 1 the milk should be boiled five minutes immediately after receiving. A mixture when prepared should be put in a covered glass fruit jar and kept on the ice. *For a baby from the sixth to the ninth month* the following mixture will be found useful: 24 oz. of milk, 24 oz. of barley water, 6 teaspoonfuls of granulated sugar. Feed 6 to 8 oz. at three-hour intervals, six feedings in twenty-four hours."—(From Kerley's *Treatment of Diseases of Children.*)

OBSTETRICS.

1. *Hysterectomy* is removal of the uterus.

The INDICATIONS FOR HYSTERECTOMY are given as follows: *For the abdominal operation:* All solid or cystic tumors of the uterus; cancer; uterine rupture during labor; certain conditions of puerperal sepsis; pregnancy complicated by pelvic deformity, cancer, or other serious obstacle to the passage of the child; uterine prolapse or inversion, and incidentally as a step in the removal of complicated suppurative conditions of the uterine appendages.

For the vaginal operation. Bilateral suppurative conditions of the appendages; prolapse, cancer, pregnancy with cancer before the sixth month; certain septic conditions of the uterus; certain rare conditions which may require the ablation of a small movable uterus.

For the combined operation: Cancer, certain complicated fibroids; failure to secure hemostasis from below.—(From *Reference Handbook of the Medical Sciences.*)

2. See Williams' "Obstetrics" (1909), page 191; or Hirst's "Obstetrics" (1909), page 204.

3. "Tears of the perineum destroy the integrity of the pelvic floor and result eventually in rectocele, cystocele, hemorrhoids, and displacements of the pelvic organs. If the tear involves the sphincter ani, incontinence also results. Lacerations of the cervix retard or check involution of the uterus and predispose to endometritis, menorrhagia, displacements, eversion of the cervical mucous membrane, cystic degeneration, and malignant disease. Deep lacerations of the vaginal vault may open into the base of the broad ligaments, and in the majority of instances genito-urinary fistulas are caused by traumatisms of labor. All lacerations are immediately dangerous on account of the increased liability to sepsis, while the remote results are generally due to interference with involution or the pelvic circulation and to the destruction of the normal supports of the pelvis."—(Ashton's *Gynecology.*)

7. See Williams' "Obstetrics" (1909), page 266; or Hirst's "Obstetrics" (1909), pages 404 and 407.

8. See Williams' "Obstetrics" (1909), pages 289 and 430; or Hirst's "Obstetrics" (1909), pages 424 and 824.

9. See Williams' "Obstetrics" (1909), pages 274, 278, and 280; or Hirst's "Obstetrics" (1909), pages 409 and 410.

10. See Williams' "Obstetrics" (1909), pages 815 and 821; or Hirst's "Obstetrics" (1909), pages 577 and 587.

11. (*a*) *Funic souffle* is a sharp, whistling or a blowing sound, synchronous with the fetal heart beat, heard on auscultation over the pregnant uterus.

(*b*) *Uterine souffle* is a rhythmical, soft, blowing sound, synchronous with the maternal heart beat, heard on auscultation over the pregnant uterus.

(*c*) *Ballottement* is the passive movement of the fetus *in utero*, obtained by tapping the lower segment of the uterus with the index finger.

(*d*) *Hegar's sign* consists in a thinning and softening of a segment of the body of the uterus immediately above its cervix.

(*e*) *Braxton Hicks' sign* consists of intermittent contractions of the uterus at about the fourth month of pregnancy.

(*f*) *Rasch's sign* is fluctuation felt when the hand is applied to the cervix of the uterus in early pregnancy, due to the presence of liquor amnii.

(*g*) *Jacquemier's sign* is a discoloration (dark or bluish) of the vaginal mucous membrane, noticed early in pregnancy.

12. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The *os uteri* is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Text-book of Obstetrics.*)

BACTERIOLOGY AND PATHOLOGY.

1. See Rose and Carless' "Surgery" (1908), pages 57, 7, and 8; or Da Costa's "Surgery" (1908), pages 42 and 33. See also French's "Practice of Medicine" (1910), page 1257.

2. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts.

See HYGIENE, 4.

3. See French's "Practice of Medicine" (1910), pages 316 and 320; or Osler's "Practice of Medicine" (1909), pages 131 and 134.

4. *Tumors are classified as follows:*

I. Those derived from mesoblast:
(*a*) *Benign:* Lipoma, fibroma, chondroma, osteoma, myxoma, myoma, neuroma, glioma, angioma, lymphangioma.
(*b*) *Malignant:* Sarcoma.
II. Those derived from epiblast or hypoblast:
(*a*) *Benign:* Adenoma, papilloma.
III. Cystic tumors.
IV. Teratomata.

See Rose and Carless' "Surgery" (1908), pages 202 and 211; or Da Costa's "Surgery" (1908), pages 310 and 333.

5. See French's "Practice of Medicine" (1910), pages 588 and 584; or Osler's "Practice of Medicine" (1909), pages 894 and 795.

MEDICAL JURISPRUDENCE.

1. (*a*) In gunshot wounds by *soft lead bullets*, the *wound of entrance* is often smaller than the ball (skin stretched at the moment of impact and contracted after perforation); it is depressed, and the edges are contused and inverted, and if the weapon is fired within ten feet usually are blackened from powder and contain powder grains. If the wound is much larger than the bullet it means that some foreign body has been carried in.

The *wound of exit* is everted, "triangular, linear, or stellate," and much larger than the wound of entrance.

(*b*) In gunshot wounds by *hard lead or steel bullets*, the *wound of entrance* is usually as large as the ball, the skin may be split or may be perforated, and foreign bodies are not carried by the ball into the tissue.

The *wound of exit*, if not in the region of explosive action, may be a little larger or a little smaller than the bullet, but is not noticeably larger than the wound of entrance. If within the area of explosive action, the wound of exit is much larger than the wound of entrance, and is irregular and everted.—(From Da Costa's *Modern Surgery.*)

The medicolegal significance of position and direction of wound consists in the fact that by careful study of these it may be possible to differentiate between suicidal, accidental, and homicidal wounds.

2. *Post-mortem appearances in phosphorus poisoning:* "The most common and characteristic of these are the jaundiced skin and internal organs, the ecchymoses beneath the skin and mucous membranes, and the fatty degeneration of the liver, heart, and kidneys. In addition to these there is frequently fatty degeneration of the gastric epithelium and of the capillaries of the cortex of the brain. Necrosis of the jaw bone is quite often found and sometimes new formation of bone tissue. If the poison has been taken in the solid state particles may be found adhering to the mucous membrane of the stomach and bowels, and perforations are very apt to occur at these points. If paste or match heads have been taken there may be no local inflammation, but ecchymoses and hemorrhages into the pleural cavity, pericardium, and bladder. The blood is dark and syrupy, the corpuscles disintegrated and destroyed. The yellow liver of phosphorus poisoning may be distinguished from that of acute yellow atrophy, which it sometimes resembles, by the fact that in the latter, instead of globules of fat, the cells are filled with or replaced by finely granular detritus, and the urine is loaded with leucin and tyrosin, whereas in the former but little increase in these substances is found."—(Riley's *Toxicology.*)

The chief industrial source is the manufacture of matches. The antidote is old French oil of turpentine, or solution of potassium permanganate.

3. *Effects of concentrated lye poisoning:* "A nauseous acrid taste, rapid destruction of the mucous membranes and even the deeper tissues of the mouth and throat, burning pain in the throat and stomach extending very soon to the abdomen, which becomes exceedingly tender, aphonia, vomiting of bloody mucus, frothy and with a soapy taste, pulse small and thready, surface cold and covered with a clammy perspiration, great prostration, sometimes ending with convulsions, especially with children. When potassium hydroxide has been taken it sometimes shows its specific action on the heart, causing slow, weak pulse, the patient sinking into unconsciousness. Constipation is sometimes troublesome, but generally a bloody diarrhea supervenes. The urine is scanty and alkaline, or entirely suppressed. The blood is dark and gelatinous. If the patient survives a few days, sloughing of the fauces and esophagus may occur, followed by stricture and death from exhaustion or starvation, or the stomach may have been most severely affected and death result from destruction of its functions."—(Riley's *Toxicology.*)

It belongs to the class of corrosives.

4. See Rose and Carless' "Surgery" (1908), page 252; or Da Costa's "Surgery" (1908), page 113.

5. See Williams' "Obstetrics" (1909), pages 188 and 192; or Hirst's "Obstetrics" (1909), page 191. Much will depend on: (1) the time that has elapsed between the abortion and the examination of the woman, (2) the period of pregnancy when the abortion was performed, and (3) the manner in which the abortion was performed.

6. The most important medicolegal question in connection with a will is the sanity or insanity of the testator.

7. *The order in which decomposition usually takes place in a dead body:* Mucous membrane of larynx and trachea, stomach, intestines, spleen, omentum, mesentery, liver, brain, heart, lungs, kidney, bladder, esophagus, pancreas, diaphragm, uterus.

Decomposition is hastened by: Temperature between 70° and 100° F.; moisture; air; age (in children and young people more rapidly than in adults or old people); obesity; death from accidents or violence, also in certain infectious diseases; and burial in low ground or in damp, swampy soil, or in shallow grave.

Decomposition is retarded by absence or reverse of the above conditions.

8. In *death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as gooseskin, and, if the body has lain upward of twelve hours in the water, that of the hands and the feet is sodden by imbibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood-stained), composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax the lungs, gray in color, with reddish staining, are seen to be

very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.—(Quain's *Dictionary of Medicine.*)

9. "The *general appearance* of a child that has been *born alive* at full term and respired is something like the following: The remains of the vernix caseosa are usually seen under the axilla, and behind the ears. The eyes remain partly open, and cannot be permanently closed. The ears are not so close to the sides of the head as is the case in children born dead. The hair is perfectly dry and clean, and the swelling at the back of the head (caput succedaneum) is more prominent than in the still-born. In the *dead-born* infant who has died immediately before its birth the vernix caseosa will be found, more or less, over its entire body. The eyes are closed and the ears are in close apposition to the head. The eyelids when raised close again. The mouth is closed, and from the nostrils is often observed exudation of watery blood. The hair is glued to the head. The thorax is unexpanded and flattened, and the lungs are situated at the posterior part of the thoracic cavity; they are greater in length than in breadth, and their margins are rounded; upon pressure no crepitation is elicited. Within the trachea, which is flattened, may be found a viscid mucous secretion. The remnant of the umbilical cord appears fresher looking than that of a child that has survived its birth a few hours."—(Herold's *Legal Medicine.*)

10. Mr. A. may have died of heart disease, apoplexy, thrombosis, embolism, or aneurysm. We decline to guess at the hour of his death.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE CHEMISTRY OF SYNTHETIC DRUGS. By PERCY MAY, B.Sc. 229 pages; cloth; price $2.25. Longmans, Green & Co., Publishers, New York.

A TEXTBOOK OF MEDICAL DIAGNOSIS. By JAMES M. ANDERS, M.D. 1195 pages; half morocco; illustrated; price $6.00 net. W. B. Saunders Co., Publishers, Philadelphia.

THE NATURE OF ENZYME ACTION. By W. M. BAYLISS, D.Sc., F.R.S. 137 pages; cloth; price $1.20 net. Longmans, Green & Co., Publishers, New York.

FOOD AND THE PRINCIPLES OF DIETETICS. By ROBERT HUTCHISON, M.D., F.R.C.P. 615 pages; cloth; illustrated; price $3.00 net. William Wood & Co., Publishers, New York.

THE PRACTICAL MEDICINE SERIES. Vol. II. SURGERY. By JOHN B. MURPHY, A.M., M.D., LL.D. 611 pages; illustrated; cloth; price $2.00; series of ten volumes $10.00. The Year Book Publishers, Chicago.

A NEW IDEA IN SANITATION. By J. C. SALTER. 89 pages paper.

CLINICAL ANALYTICAL METHODS. By KARL M. VOGEL, M.D. 19 pages; paper. James T. Dougherty, New York, Publisher.

MENTAL MECHANISMS. By WILLIAM A. WHITE, M.D. 151 pages; paper. The Journal of Nervous and Mental Disease Publishing Co., New York, Publishers.

EDUCATION AND PREVENTIVE MEDICINE. By NORMAN EDWARD DITMAN, Ph.D., M.D. 73 pages; paper; price 25c. The Columbia University Press, Publishers, New York.

THE PRINCIPLES AND PRACTICE OF BANDAGING. By G. G. DAVIS, M.D. 128 pages; illustrated; cloth; price $1.00 net. P. Blakiston's Son & Co., Philadelphia, Publishers.

NEURASTHENIA. By GILBERT BALLET. 408 pages; illustrated; cloth; price $3.00 net. William Wood & Co., New York, Publishers.

JOINT TUBERCULOSIS. By LEONARD W. ELY, M.D. 243 pages; illustrated; cloth; price $2.50 net. William Wood & Co., New York, Publishers.

DISEASES OF THE SKIN. By JAMES H. SEQUEIRA, M.D. 539 pages; with 44 plates in color and 179 other illustrations; price $8.00 net. P. Blakiston's Son & Co., Philadelphia, Publishers.

PROGRESSIVE MEDICINE. By HOBART AMORY HARE, M.D., and LEIGHTON F. APPLEMAN, M.D 397 pages; illustrated; paper; price $6.00 per annum. Lea & Febiger, Philadelphia and New York, Publishers.

AMERICAN PRACTICE OF SURGERY. VOL. 8. Edited by JOSEPH D. BRYANT, M.D., LL.D., and ALBERT H. BUCK, M.D. 1,146 pages; illustrated; cloth. William Wood & Co., Publishers, New York.

MEDICAL REVOLUTION. By SYDNEY W. MACILWAINE, M.R.C.S., L.R.C.P. 162 pages; price 2/6 net. P. S. King & Son, London, Publishers.

MERCK'S MANUAL. Fourth edition; 493 pages; paper. Merck & Co., St. Louis, New York and Rahway, Publishers.

PROCEEDINGS OF THE CANAL ZONE MEDICAL ASSOCIATION FOR THE HALF YEAR, 1910. April, 1910, to September, 1910. 150 pages; paper. I. C. C. Press, Mount Hope, C. A., Publishers.

THE PRACTICAL MEDICINE SERIES. Vol. III: The Eye, Ear, Nose, and Throat. Edited by CASEY A. WOOD, C.M., M.D., D.C.L.; ALBERT H. ANDREWS, M.D., and GUSTAVUS P. HEAD, M.D. 365 pages; illustrated; cloth; price $1.50. The Year Book Publishers, Chicago, Publishers.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. By Dr. L. KATZ. 80 pages; paper; illustrated; price 6 M. Curt Kabitzsch, Würzburgh, Publisher.

THERAPEUTIQUE USUELLE DU PRATICIEN. By ALBERT ROBIN. 530 pages; paper; price 8 fr. Vigot Frères, Paris, Publishers.

HEALTH HINTS. By E. R. PRITCHARD. 153 pages; cloth; price 50 cents net. The Reilly & Britton Co., Chicago, Publishers.

ONE THOUSAND SURGICAL SUGGESTIONS. By WALTER M. BRICKNER, B.S., M.D. 225 pages; cloth; bound semi-de luxe $1.00, full de luxe leather $2.25. Surgery Publishing Co., New York, Publishers.

SCHUTZPOCKENIMPFUNG UND IMPFGESETZ. By Prof. Dr. MARTIN KIRCHNER. 158 pages; paper. Richard Schoetz, Berlin, Publisher.

THE PREVENTION OF MALARIA. By RONALD ROSS. D.P.H., F.R.C.S., D.Sc., LL.D., F.R.S.C.B. 669 pages; cloth; illustrated; price $5.00 net. E. P. Dutton & Co., New York. Publishers.

YEARBOOK OF THE UNITED STATES DEPARTMENT OF AGRICULTURE. 1910. Published by Government Printing Office, Washington. 711 pages; illustrated; cloth.

UNSOUNDNESS OF MIND. By T. S. CLOUSTON, M.D., LL.D., F.R.S.E. 360 pages; illustrated; cloth; price $2.50 net. E. P. Dutton & Co., New York, Publishers.

TRANSACTIONS OF THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS. Vol. V. 400 pages. Published for the Society by Frederick H. Hitchcock, New York.

LITORA ALIENA. By MEDICUS PEREGRINUS. 78 pages; paper; price 50 cents. W. M. Leonard, Publisher, Boston, Mass.

HOW OLD THE NEW. By Dr. JAMES J. WALSH. 457 pages; cloth; price $2.00 net. Fordham University Press. Publishers.

Medicolegal Notes.

Father's Liability for Medical Treatment to Emancipated Minor Son.—In an action by a physician against the father of a boy of 20 for compensation for services in attendance on the latter while suffering from typhoid fever the defense was that the boy was emancipated and there was no contract with the father. In the same year the boy had left his father's home in Missouri and gone to Oregon. It was held that he was emancipated and that the fact that the physician did not know that he was no longer under parental control did not affect the defense. The plaintiff knew when the boy applied to him for assistance that he was not living with his parent. He was informed that the father lived in Missouri, so that the arrangement between the father and son, under which the boy had left home, was a matter the plaintiff should have inquired into before rendering the services to the boy on the credit of the father. It was not necessary that he should have actual knowledge of such an arrangement. The father wrote to the hospital in answer to a letter notifying him of his son's sickness, "I have a dear boy in your institution sick with fever. I have sent him some money and will send him more soon. You will give him all the attention you can and greatly oblige a father so far away, and kindly let me know from time to time how he is getting along." It was held that this did not constitute a promise in writing to pay for the services, as there was no evidence that the letter in any wise changed the relation of the parties or the terms of the existing contract with the boy under which he was being treated, or that any additional attention was given the boy on account thereof. Brosius v. Barker (Mo.), 136 S. W. 18.

Waiver of Privilege by Patient as to One Medical Attendant Does Not Admit the Evidence of Others.—In an action for damages for personal injuries received while alighting from a train a physician who attended the plaintiff after the injury testified that she suffered from a prolapsus of the uterus, which might have resulted from her fall. The defendant offered to prove by two physicians who had attended the plaintiff about two years prior to the injury that she had sustained a displacement of the womb at that time. Objection by the plaintiff to the admission of this testimony was properly sustained. The Arkansas statute, Kirby's Dig., § 3098, prohibiting a physician from being compelled to disclose information acquired while treating a patient in a professional character, necessary to enable him to prescribe, was enacted for the patient's benefit. It is a privilege which the patient alone may waive. When it is waived by the patient as to any particular witness the adversary is entitled to the benefit of the waiver as to such witness, but is not entitled thereby to call another physician who treated the patient at a different time to testify relative to the matter. Missouri & N. A. R. Co. v. Daniels, Arkansas Supreme Court, 136 S. W. 651.

Information Charging Practising Without License Must Negative the Exceptions in the Statute.—An information charged that the accused treated and professed to heal a certain named patient "without having a certificate or license issued by the State Board of Health, and filed in the office of the clerk of Custer County, Nebraska, as required by law." There was no allegation that the accused resided in Custer County. The act requires a license to be filed in the county where the licentiate resides or in which he intends to practise. The information was held to be fatally defective because it did not negative the fact that a license issued by the State board might have been filed in the office of the county clerk of the county where the accused resided. Every fact stated in the information might have been true and the accused be not guilty. Wilson v. State, Nebraska Supreme Court, 131 N. W. 223.

Evidence of Failure to Attend Accouchement as Promised Admissible.—In an action against a physician for negligence in failing to attend, in accordance with his promise and employment, the accouchement of the plaintiff, who had received a jar while alighting from a street car which brought on premature labor, the plaintiff's declaration alleged that laceration of the cervix and rupture of the perineum resulted from the defendant's neglect. It was held error to refuse, as bearing on the issue of negligence, the plaintiff's offer of evidence that after calling several times up till 7 P.M., when he promised to return at 11 P.M., or earlier, and, although telephoned to several times after that hour, he did not return until 2 A. M., after the child was born. Adams v. Henry, Michigan, Supreme Court, 131 N. W. 62.

Nonassenting Father's Liability for Operation on Infant Child at Request of Mother.—In a suit in quantum meruit for the reasonable value of professional services of a surgeon in performing an operation on the defendant's infant child it appeared that the defendant's little daughter had been suffering from liver trouble and was brought from her home to St. Louis by her mother and the family physician for treatment by the plaintiff. After an examination the plaintiff and the family physician diagnosed the malady to be an abscess on the liver and advised an operation to save the patient's life. To this the defendant's wife consented. The operation was performed and about two quarts of pus removed. The patient succumbed a day or two after, but it was conceded that the operation was performed with skill and the death occurred from weakness resulting from the disease. The defendant resisted payment of the plaintiff's charge solely on the ground that the operation was performed without his knowledge or consent. It was conceded that the operation was necessary to save the child's life, but was, of course, a dangerous one in the weakened condition of the patient. There was evidence for the defendant that he had objected to an operation before his wife left home with the child, but that fact was not communicated to the plaintiff. It was held that in the circumstances of the case the services rendered were necessaries, for which the law implied an obligation on the part of the father to pay when performed at the instance and request of the mother. The case was distinguished from that of Detwiler v. Bowers, 9 Pa., Super. Ct., 473, where it was said that a surgical operation of doubtful advantage is not a necessary for which a nonassenting father is liable upon an order given to the surgeon by the wife. In that case the malady was a cancerous tumor, and the parents had been advised that the disease would immediately reveal itself again, though an operation were had. That prediction came through, and the court deemed that the operation, known to be of doubtful advantage, did not come within the category of necessaries furnished the child for which the parent should answer.—French v. Burlinghame (Missouri), 134 S.W. 1100.

Masseur, as Such, Does Not Require Certificate.—In a prosecution for practising medicine without having filed the required certificate, the defense was that the accused was practising as a masseur. The court charged the jury that if the defendant did not charge for his services as a masseur, or for treatment by any method or system, and receive pay therefor, he should be acquitted, and that a masseur, in his particular sphere, was not required to secure a certificate. This charge, it was held, fairly submitted the defense. Newman v. State, Texas Court of Criminal Appeals, 134 S.W. 688.

Proving Existence of Nervous Disease.—Affection of the nervous system is a disease whose diagnosis and treatment call for the experienced physician. In estimating damages, therefore, in an action for injuries a jury may accordingly properly use the fact that the plaintiff's attending physician did not testify as a presumption of fact against the plaintiff. Steinert v. Whitcomb (Conn.), 79 Atl. 675.

Medical Expert's Evidence as to Injuries—Bias May Be Shown.—A physician who had treated an injured woman was asked as an expert what would be the effect of a woman being thrown out of a seat in a street car upon the lower end of her spine and buttocks. The plaintiff had testified to her fall and described the resultant injuries. There was nothing in the question requiring the physician to commingle knowledge gained as a physician with his opinion as an expert. He might give the probable results of the injury or the causes which might produce certain described conditions. Where the testimony of a medical expert for the defendant conflicts with that of the expert for the plaintiff it is permissible to contradict the former by reason of bias and to show that he held a similar position with another company. Witty v. Springfield Traction Co. (Missouri), 134 S.W. 82.

Itinerant Vendors of Drugs Do Not Require Certificates for Practising Medicine.—The Arkansas statute regulating the practice of medicine provides that any itinerant vendor of drugs intended for the treatment of disease "or" who may, by writing, print, or other methods, profess to cure diseases by any drug, shall, unless he has a certificate, be in violation of the law. It also provides for an examining board to issue certificates and makes it an offense to practise medicine without a license. In view of the general scope of the act, and that, if construed otherwise, the clause "who may by writing, print, or other methods profess to cure disease," etc., would be rendered ineffective, the act was construed to require only those itinerant vendors of drugs who profess to cure disease to secure a license; the word "or" being construed as "and." Williams v. State, Arkansas Supreme Court, 137 S. W. 927.

Unlawfully Practising Medicine—Sufficiency of Indictment.—Under the Texas statute defining and regulating the practice of medicine, an indictment charging the defendant with unlawfully practising medicine without having properly registered his authority for so doing, and treating and offering to treat physical disease and disorder, and making a charge therefor, is sufficient. Young v. State. Texas Court of Criminal Appeals, 134 S.W. 736.

Negativing Statutory Exceptions in Prosecutions for Practising Without License.—Missouri Rev. St., 1909, § 8315, makes it a misdemeanor to practise medicine or surgery without a license from the State Board of Health, but provides that physicians registered on or before March 12, 1901, shall be regarded as registered physicians for the purposes of the act. In a prosecution under the act it was held that an information charging that the accused, not being a registered physician, and having no license from the State Board of Health, did indicate that he was engaged in the practice of medicine, and that he treated the sick, etc., for compensation by offering to treat a specified person for a certain disease in consideration of a designated amount, was fatally defective for failing to negative the exception. The statute provides for a fine on conviction of not less than $50 nor more than $500, or imprisonment for not less than 30 days nor more than a year, or both. It was held that a judgment that the accused be imprisoned for 30 days, pay the costs accrued in the case, and stand committed until the sentence be complied with, that he pay to the State a fine of $500 with the costs accrued and that execution issue therefor, is defective as apparently imposing separate sentences adjudging two sets of costs, and leaving it a matter of doubt as to what punishment is actually inflicted. State v. Hellscher (Missouri), 135 S. W. 959.

Contract for Fee Contingent on Damages Recovered by Invalid.—A person injured in a railway collision made a contract with the physician who attended him to give him for his professional services one-third of any sum he might receive from the railway company as damages and to pay him a further sum in addition thereto if the claim was settled out of court for $2,000 or more. The claim was settled for $1,800 and the physician subsequently sued the party injured for the balance of the agreed on one-third. It was held that the contract was invalid as in contravention of public policy. The amount to be obtained from the railway company must depend principally upon the testimony of experts like the plaintiff, and the circumstances of the case and the agreement made showed that it was contemplated that the plaintiff should be a witness in case of suit, and should give a history of and opinion upon the case in the event of a proposed settlement. The plaintiff's interest in the amount of the damages would, therefore, tend to color his testimony. Sherman v. Burton, Michigan Supreme Court, 130 N. W. 667.
